of luteinization (McCarthy and Becker 2002). The CL is a transitory endocrine gland responsible for the production and secretion of progesterone and, to a lesser degree, estrogen (Stocco et al. 2007). The secreted progesterone, along with estrogen, activates a negative feedback loop on the hypothalamus and pituitary gland, inhibiting GnRH, LH, and FSH production and secretion (Fig. 2). As a result of this, a decrease in secreted estrogen occurs, which ultimately leads to the termination of reproductive behaviors following ovulation. In the event of successful conception, the CL remains functional and secretes steroid hormones throughout pregnancy. Should conception not occur, the CL will continue to secrete progesterone throughout the luteal phase until the CL undergoes degradation during diestrus (McCarthy and Becker 2002). With this, the negative feedback loop is terminated and GnRH secretion is initiated, starting a new estrus cycle. In certain mammal species, a period of sexual inactivity follows diestrus and the parturition event, known as anestrus. During anestrus, the HPG axis secretes low hormone levels, thus inhibiting ovulation and reproductive activity.

### Reproductive Behaviors During the Estrous Cycle

Beach (1976) proposed that female sexual behaviors be divided into three components: attractivity, proceptivity, and receptivity. **Attractivity** is defined as the stimulus value of a female to a male, which is measured by male preference of a female, and often calculated by the extent to which a male prefers to be in close proximity to a female conspecific. The stimuli basis of attractivity can be both behavioral and non-behavioral (visual, chemosensory; Thomas 2011). **Proceptivity** refers to a range of female solicitation behaviors towards male conspecifics which might lead to an increase in male mountings (Blaustein and Kiesecker 2002). In contrast to attractivity, proceptivity is largely focused on female preference and includes activities such as female–male grooming and/or female pacing and

presenting to name a few. Such affiliation behaviors play an important role in establishing a close proximity of females to a selected male, increasing the chance of intercourse. A well-known example of this is lordosis behavior, where females lower their forelimbs, extending their rear limbs and arch their spine in order to attract and facilitate mating (Pfaus et al. 2015). Both attractivity and proceptivity are limited to the **proestrus** period of the estrus cycle. **Receptivity** reflects the stimulus value of a female individual for eliciting an intravaginal ejaculation from a male (Nelson 2011). During this activity period, female individuals display a specific set of behaviors which assist, and are often necessary, for fertile copulation with male conspecifics. In the majority of mammals, receptive behaviors are initiated shortly prior to the ovulation event and continue until shortly thereafter; this period is referred to as estrus (Fig. 2). In a number of species, proceptivity and receptivity frequently overlap, with females engaging in male soliciting, directly followed by female posturing and copulation (Nelson 2011).

### Postpartum Estrus

**Postpartum estrus** (PPE), a subsequent reproductive period immediately following parturition, can be a major reproductive strategy employed by mammals to ensure maximum reproductive output; this is especially true for small bodied mammals with a short lifespan (Conaway 1971). Despite the obvious advantages of including PPE, it can be energetically expensive and costly for females in two ways. Firstly, the activation of reproductive activity during PPE coincides with lactation and raising of young, both of which constitute an energetically expensive life history stage in a female (Speakman 2008). As a result of this, females must increase the time spent on foraging behaviors to account for the additional energy requirements or face a decrease in body condition and survival likelihood. Secondly, females must divide their time and attention during PPE between two mutually exclusive activities, raising young and mating activities. As maternal care is directly linked to survival rate of

newborns, entering PPE while younglings are still dependent on a female can be a costly endeavor which leads to litter loss (Witt et al. 1990). Thus PPE will only be activated should the necessary environmental and social factors be present to support it. For example, prairie vole females (*Microtus ochrogaster*), will activate PPE only if a reproductively active male is present (Carter et al. 1986). PPE requires the activation of the HPG axis and the secretion of reproductive hormones to prepare the uterine endometrium for copulation and embryo implantation. In the absence of such activation, females may be unable to enter estrus and successful mating may be absent (Scheun et al. 2016). In contrast to increased reproductive output, PPE may also be used as a back-up/fall back mechanism should litter loss occur (Steyaert et al. 2014). The flexibility with which certain mammal species engage in PPE indicates that PPE acquisition or loss may be one of the most easily made reproductive adjustments in mammals (Witt et al. 1990).

## Ethel Tobach

Gary Greenberg

Wichita State University, Wichita, KS, USA

Ethel Tobach (née Idels) was born on November 7, 1921, and passed away on August 14, 2015. Her passing brought to a close an important era in comparative psychology. This essay is not intended to be an obituary, but rather a biography and a paean to a scientist, a scholar, a social activist, and despite her curmudgeonly side (something familiar to all who knew her), a genuinely good person. She was my friend and mentor for over 25 years following the completion of my doctoral degree at Kansas State University in 1971.

(Much biographical material in what follows has been adapted from Greenberg 2015; Lewis 2010; Unger 2009). Born in Ukraine, the pogroms of Russia's White Army forced Ethel's family to move to Palestine soon after her birth. Following the death of her father when she was 9 months old her mother emigrated with her to Pennsylvania, USA. They did not stay there long, finally settling in New York City when Ethel was 10. She remained a New Yorker the rest of her life, living for many years just a short walking distance from the American Museum of Natural History, where she was to spend her entire career.

She inherited her social and political activism from her mother and this was to be one of her lifelong defining characteristics, a result of which was her cofounding in 1971 of Psychologists for Social Action which later morphed into Psychologists for Social Responsibility (Miller 2008) described at this website (<http://www.psysr.org/>). Important in her life's work was her leadership in psychology activist groups through which she sought and worked for constructive public policies, nuclear disarmament, and peace building. She was, in this regard, the epitome of a socially responsible scientist. The award she received from the American Psychological Association in 2003 (Gold Medal Award for Lifetime Achievement in Psychology in the Public Interest carried

this citation: "[Dr. Tobach] has exposed the unsound science and social damage of genetic determinism institutionalized as racism and sexism." She was, indeed, one of her generation's ardent and widely recognized spokespersons against the pernicious ideas of the genetic determinism of behavior.

Interestingly, she came to psychology late in her education. Her bachelor's degree was from Hunter College of the City University of New York in 1949. Not surprising she was a Phi Beta Kappa student. At Hunter her interests were in English, economics, pre-med, and educational psychology. It was only later that she switched her interests to comparative psychology, the focus of her productive career. Professors tried to steer her away from psychology telling her that there were no women in that field. Her response, in her typical style, was, "I don't care about that." Charles Tobach, an independent photo journalist, whom she married in 1949, encouraged her to pursue doctoral work at New York University (NYU). Characteristic of the times, NYU was wary of accepting married women. It was there that she met and was supervised by T. C. Schneirla, at the time among the preeminent comparative psychologists of the day. She completed her doctoral work with him in 1957.

Tobach began her career at the Department of Animal Behavior at New York's American Museum of Natural History (see Greenberg et al. 2004) joining Schneirla who was working there at the time. She spent her entire career there and though retiring as Curator Emerita in 1991, she worked and maintained her association with the Museum almost until the time of her passing. Her laboratory at the Museum was a warren of equipment and animals. She had worked at various times with rats, mice, gerbils, spiny mice, and the marine mollusk, *Aplysia*. Schneirla, famous for his work with ants, championed working between naturalistic field settings and laboratories, an approach favored as well by Tobach. I had accompanied her on three field trips to Puerto Rico to study and collect *Aplysia* for shipment back to her laboratory in New York. The photo accompanying this essay shows her transcribing field notes on one of those field trips (Fig. 1).

**Ethel Tobach, Fig. 1** Ethel Tobach transcribing field notes after a full day observing *Aplysia* in waist-deep water (La Parguera, Puerto Rico. Early 1980s. Photo by the author)

While her base was at the Museum at various times she held academic positions at New York University, Yeshiva University, City College of New York, State University of New York, and several other institutions, some outside the USA. She had visiting research assignments at numerous international laboratories. Ethel Tobach was famous for mentoring high school students in her laboratory as well as promising undergraduate and graduate college students and occasional postdoctoral students, of which I was one (Greenberg 2015). In this regard, she was known to be an exciting teacher and lecturer (Miller 2008), something I can attest to.

Her activism began to show itself in her early 1920s during WWII when she was employed making lenses for bombsights. It was then that she became active in her lifelong promotion of trade unions. Despite her pacifism her anti-Nazi feelings impelled her to join the Women's Army Corps and was assigned to a New York psychiatric

hospital. The bombings of Hiroshima and Nagasaki firmly cemented her tireless and lifelong peace activist activities.

Tobach was a Fellow of several divisions of the American Psychological Association including 6 (Physiological and Comparative Psychology, President 1984–85) and 48 (The Society for the Study of Peace, Conflict, and Violence, President 2004). She held membership in several organizations which reflected her many interests: member and president (later president emerita) of the International Society for Comparative Psychology (which she founded), the Animal Behavior Society, the American Association for the Advancement of Science, the Association for Women in Science, and several others. She held elective offices in the New York Academy of Science, the American Psychological Association, the international Union of Psychological Sciences, the Eastern Psychological Association, the Association for Women in Psychology to UN/DPI/NO, as well as other scientific and social activist organizations. In her service to the profession of psychology she held editorial positions on publications such as *Animal Behavior*, *Biological Psychiatry*, *Journal of Comparative Psychology*, *Advances in Comparative Psychology*, and also edited the book series *Genes and Gender* and the *T. C. Schneirla Conferences*.

Her several awards and recognitions include the Kurt Lewin Award from the American Psychological Association's Society for the Psychological Study of Social Issues, which acknowledged her "outstanding contributions to the development and integration of psychological research and social action" and the American Psychological Association's Gold Medal Award for Lifetime Achievement in Psychology in the Public Interest (2003).

Her body of scholarly and research work was impressive, with over 117 professional articles, books, and book chapters. She believed her major contributions to comparative psychology to include demonstrating that susceptibility to TB is directly related to behavioral stress; that the olfactory system plays a role in newborn rats; that the inking response of *Aplysia* is not an instinctive defensive reaction; and that serotonin

deficiency in fawn-hooded rats is related to taste. However, all who were familiar with her and her work acknowledge that she was known for far more significant contributions to scientific understanding than that. Beyond her research publications and essays on various aspects of psychology she had edited several important books: The *Genes and Gender* series (Gordian Press); The *T. C. Schneirla Conference* series (Erlbaum Press); *Selected Writings of T. C. Schneirla* (W. H. Freeman); and *Development and Evolution of Behavior: Essays in Memory of T. C. Schneirla* (W. H. Freeman). [See Unger (2009) for a list of Tobach's publications and see Lewis (2010) for a list of references about Tobach.]

The publication and popularity of *Sociobiology*, Wilson's (1975) attempt at biologizing the social sciences, represented in her words that "the study of the evolution of behavior as a psychological discipline [had] been eclipsed by recent developments in evolutionary biology" (Innis 2000, p. 54). This coupled with her outstanding international reputation as a psychologist provided the impetus for her to found the International Society for Comparative Psychology (ISCP) in 1980 (Innis 2000). In the letter of invitation to join the society sent to comparative psychologists around the globe Tobach said, "[w]e aim toward an openness of theoretical orientation in comparative psychology and so the 'psychology' of comparative psychology may be defined variously. The 'comparative,' however, is firmly based on evolutionary principles" (Innis 2000, p. 54). The first meeting, held in Canada in 1983, brought together psychologists from the USA, Japan, Italy, Germany, and Colombia. It was again her global reputation that gained the ISCP almost immediate acceptance as an affiliate organization of the important International Union of Psychological Sciences at a 1984 meeting of the International Congress of Psychology in Acapulco, Mexico. The ISCP still holds biennial meetings around the world and publishes a journal also founded by Tobach, the *International Journal of Comparative Psychology*.

To be sure, Ethel Tobach was well known and well respected in global science circles. This anecdote provided by Howard Topoff (2016,

Personal communication), one of her close colleagues and coworkers at the Museum of Natural History, is a fitting way to sum up her career and provides a glimpse into the kind of person Ethel Tobach was. Topoff was Schneirla's last doctoral student – they shared that relationship in common.

The 1973 Nobel Prize in Physiology or Medicine was awarded jointly to Karl von Frisch, Konrad Lorenz and Nikolaas Tinbergen "for their discoveries concerning organization and elicitation of individual and social behaviour patterns." During lunch in the Seminar Room of the Department of Animal Behavior at The American Museum of Natural History, Ethel had an idea. Since the Museum's Animal Behavior program was a collaboration with the City University of New York, let's have CUNY invite Konrad Lorenz to come to New York to give a presentation. I said great idea, and that I would contact the office of the President to make an appointment. Ethel said "nah. I know him very well. Let's just go there after lunch." We did, he was in his office, and when he heard that Ethel Tobach was waiting to see him, he ushered us right in. So, she was great friends with the President of The City University of New York. Actually, not so surprising, Ethel seemed to know everyone, everywhere. Politicians, union leaders, deans – wherever she went, people would recognize her, wave, and yell "hi Ethel." And she would say "hi" back, calling out their name. You would think that all of New York City was her family. "Who was that" I once asked her when leaving the theater. "Oh, just the New York Commissioner of Cultural Affairs but, we don't know each other that well." I said "Ethel, you're not SO famous that you have to be modest."

## Ethics

Raymond Anthony  
Department of Philosophy, University of Alaska  
Anchorage, Anchorage, AK, USA

## Introduction

The moral status and treatment of 17 macaque monkeys, used for experiments in neuroplasticity and housed at the Institute of Behavioral Research in Silver Spring, Maryland, became the center of attention between 1981 and 1991 (Sideris et al. 1999). As one author put it, the case of these monkeys is responsible for “launching” the Animal Rights Movement in the United States (Guillermo 1993). The Silver Springs monkeys incident raised questions about the limits on what can and should be done to research animals, and the quality of both veterinary care and husbandry that is owed to research animals. Public outcry along with the efforts of the animal rights group PETA (People for the Ethical Treatment of Animals), including the release of its self-produced 26 min film, *Unnecessary Fuss*, led to an amendment in 1985 to the US Animal Welfare Act (introduced as the *Improved Standards for Laboratory Animals Act* as part of the Food Security Act (Farm Bill) of 1985), changes to the US Public Health Service Policy, and the formal introduction in 1986 of Institutional Animal Care and

Use Committees (IACUC) (Sideris et al. 1999). Per the direction of Congress, an information service to provide resources to both the general public and the research community on the care and welfare of animals and alternatives as expressed by the 3Rs (reduction, refinement, and replacement) was established at the National Agricultural Library (now the Animal Welfare Information Center).

The Silver Springs monkeys case highlights the importance of having the highest ethical standards for governing how we manage, care, house, and treat animals, especially those whom we have invited to be part of our families as companions or pets, and animals in the laboratory, agricultural, or clinical settings. While a good deal of common ground in making ethical judgments about how we should treat animals and promote their welfare have emerged since the 1980s (DeGrazia 1999), there is still no universal agreement regarding the moral status of animals, and ways to strengthen the ethics behind human-animal relationships continue to be debated. While we continue to struggle over claims that there is something distinctive about human beings that justifies difference in moral significance or treatment from members of other species, advances in philosophical, ethical, and legal arguments challenging the status of animals as mere property, research instruments, or mere resources are more frequent and warrant serious moral consideration (see, for example, Quebec's Bill 54 (2015) that officially recognizes animals as sentient beings with biological needs, and the EU's Lisbon Treaty (2009)).

Below, a discussion related to important developments in the study of ethics and animals follows, as well as other ways to think philosophically about animals and their interests.

## What Is Animal Ethics?

This entry has been developed with a view to aid nonphilosophers (e.g., scientists who are sensitive to the philosophical complexities regarding animal consciousness, cognition, and their moral status) navigate some of the main highlights in the philosophical literature on ethics

and animal ethics, with a view to references that might be most relevant to their own research and scholarship.

*Ethics* concerns beliefs or attitudes regarding right and wrong actions, and the rules or standards for governing conduct. It also concerns what constitutes good and bad persons or character. Ethics helps us to better understand human nature and the proper scope of our moral obligations to other individuals, groups, and entities. Ultimately, ethics involves the study of how to live well, to be good at being human, if you will. Ethical inquiry on a particular subject helps us to deliberate and make judgments about the nature of right and wrong and to reflect on the norms or standards of acceptable behavior that support right relationships with others during the course of our day or a lifetime, including whether or not to accept the moral claims or arguments of others and what ethical commitments to value. Our ethical commitments promote respectful and caring actions towards others, and proscribe unfair distributions of benefits to the already disadvantaged or actions that would increase harms or burdens to others. Ethics also help us aspire towards laudatory behavior and activities, such as helping those in need, whether or not they are distant to us temporally, spatially, or species-wise. Ethics addresses issues around health and well-being, pain and suffering, rights and freedoms, hope, and life and death and circumscribes actions that are morally obligatory, permissible, forbidden, and supererogatory.

*Animal ethics* refers to the ongoing project to understand our relationship to nonhuman animals. Animal ethics brings together the above-mentioned ethical underpinnings and applies them to human-animal relationships. Animal ethics highlights ethical challenges that can constrain healthy human-animal interactions, especially in cases where animals are treated as resources or when interspecific conflicts of interests persist. Animal ethics is a sub-branch of applied ethics that specializes in animal issues. In particular, animal ethics debates the bases of moral consideration of animals (i.e., membership into the moral community and moral considerability) and justification for certain treatment

or use, which may or may not involve inflicting pain, suffering, and death upon them. Philosophers working in animal ethics are concerned about animal husbandry and their welfare, the use of animals in agriculture and medicine, and the impacts of environmental policies, biotechnology, and precision or networked technologies on animals. Animal ethics informs our treatment of animals and seeks answers to a range of ethical questions regarding how we ought to deliberate about their welfare and dignity, and when we have to utilize practices that cause them pain, suffering, or death, do we have defensible reasons for doing so. More broadly, this area of applied ethics is concerned with whether:

- Animals have moral standing in their own right. And if so, what kind of responsibilities do human beings have towards them
- We have responsibilities to only individual animals or also to species or populations of animals
- The grounds for human uses of animals is defensible

Philosophers working in animal ethics strive to promote healthy human-animal relationships and offer guidance to humans, qua moral agents, on how they should treat animals in our “mixed communities” (Midgley 1983). Animal ethicists struggle with how we should balance our duties to animals against other kinds of duties (to other humans and the planet) as well as basic questions like whether animals should be used in biomedical research, teaching or entertainment, and if they should be raised for food or kept as pets.

Today, animal ethics questions have also fallen to both experts and laypersons alike – scientists, veterinarians, farmers, pet owners, food consumers, and policy makers. Though the core of animal ethics is still moral philosophy, fully informed animal ethics must be performed with a competent grasp of the relevant empirical facts and other nonmoral issues (Fraser 1999), including, but not limited to, the veterinary, cultural, scientific, legal, and technological domains that inform us about the capacities of animals and how human action may harm animals. Progress in

addressing healthy human-animal relationships require interdisciplinary work by philosophers and scientists alike, namely, finding novel ways to integrate emerging empirical details about what matters to animals with philosophical arguments regarding just what evidence (e.g., phenomenological, epistemological, and metaphysical) should be employed to establish their place in the moral community with moral claims on human beings, including proper treatment.

Returning to the nature of ethics, our view of which ethical standards are laudatory is connected inextricably to our moral beliefs and values. Here, values are ideas that direct our actions. Values guide us by giving meaning to our lives as well as by providing the blueprint of how to be good and live well with others. Values impress on us what matters and why they do. Values suggest both an inevitability and inescapability regarding facing ethical issues and meeting our ethical commitments. This includes reflecting on what to value, the shape of moral concepts themselves, addressing pressing ethical questions, like fair distribution of scarce health care and ecosystem resources and environmental stewardship, and how we should treat each other. Duties to pets or companion animals (Ellingsen et al. 2010), the permissibility of using animals in teaching and biomedical research (Greek and Greek 2010; Tannenbaum and Rowan 1985), and the moral status of raising animals for food are among notable “pressing issues” that seem to have gained ethical currency and prominence and captivated our public imagination and moral consciousness (Riffkin 2015; Loveridge 2013; Prickett et al. 2010; Fraser 2008b; Sandøe and Christiansen 2008).

Moral judgments, principles, and rules direct conduct and shape moral practices and provide benchmarks for assessing the moral worth of others. Our moral judgments, rules, principles, and standards regarding animals are informed by religion, political ideology, law and public policy, level of education, economics, family and peers, societal factors like customs and norms, our relationship to technology, how animals promote personal aspirations and self-efficacy, and how we judge benefits and harms (Guerrini 2016; Deemer

and Lobao 2011; Naald and Cameron 2011; Kendall et al. 2006). Ethical standards inform professional codes of conduct and processes, such as those that might govern Institutional animal care and use committees (IACUCs), which are tasked with ensuring ethical oversight of research employing animals. These standards have also influenced OIE Animal Welfare principles, the leading intergovernmental organization responsible for improving animal health worldwide, and form the basis of numerous other governance initiatives about animals (e.g., Article 13 of Title II, of The Lisbon Treaty) (2009), ([https://ec.europa.eu/food/animals/welfare\\_en](https://ec.europa.eu/food/animals/welfare_en)) and national or state/provincial animal protection laws.

Ethical theories that apply in the human case (e.g., deontology, utilitarianism, virtue ethics, feminist ethics, contractarianism) have been used to provide justification for respectful treatment of animals. Ethical approaches under the heading of “animal welfare utilitarianism,” for example, require that we choose actions resulting in the best possible balance of benefit versus harm for all sentient beings, including some animals. In the research setting, this choice advocates for the now familiar 3Rs of reduction, refinement, and replacement (Russell and Burch 1959). A rights-based approach, on the other hand, requires that we respect the inherent worth of certain animals (Regan 1983; Russow 1990, 1999; Sideris et al. 1999).

Empiricists like sociologists, anthropologists, historians, and psychologists also study matters concerning ethics and provide descriptive accounts of what people actually believe, what preferences they hold, what customs they practice, which moral standards they support, and catalogue how people behave (e.g., Herzog 2011; Bradshaw 2009; Arluke and Sanders 1996). The scientific method is employed to carry out these investigations, and is used by these researchers to uncover links between beliefs, attitudes, and action or to understand the causal reasons why people hold the beliefs, attitudes, and preferences that they do that influence their actions. A key difference between the normative work that ethicists do and scientific

investigations undertaken by scientists is that while ethicists are concerned with normative matters such as “how ought we to live” or “how should we treat sentient beings,” scientists are concerned about empirical matters, i.e., what is the case. For example, animal scientists might study what husbandry conditions are suitable for goats to thrive (e.g., pen size, enrichment opportunities, including exposure to conspecifics).

## Ethics and Animals: A Glance at Where We've Been

Since the 1970s, the academic community has given more and more attention to the ethical nature or shape of the relationship between human beings and animals. Much of this has been spurred on by greater interest in the inner lives of animals, including the distribution of animal consciousness across various species, and research regarding animal emotion, pain, behavior, and cognition, from both laypersons and those working directly with animals in the sciences (Boly et al. 2013; Allen and Bekoff 1997; Pepperberg 1999). In 1964, Ruth Harrison's *Animal Machines*, preceded by Rachel Carson's *Silent Spring* (1962), helped to fuel both public concern and academic interest over human responsibility over the plight of animals and the environment. Standing on the shoulder of Carson and Harrison, Godlovitch, Godlovitch, and Harris at Oxford University published a series of philosophical essays in *Animals, Men and Morals* (1971) that highlighted the ethical terrain involving animals. Subsequently, in 1975, Australian philosopher, Peter Singer, published the first edition of *Animal Liberation: A New Ethics for Our Treatment of Animals*, which raised both public awareness and moral critique regarding then “current day practices” involving animals. Since then, there have been a number of influential philosophical and ethical expositions on animals and human-animal interactions. They have been inspired by and have in turn inspired the thinking of some of the professionals in direct proximity to animals, namely, researchers and animal scientists, cognitive ethologists, and veterinarians.

Philosopher Lilly-Marlene Russow (1999), for example, in *Ethical Implications of the Human-Animal Bond in the Laboratory* invites researchers to consider bolstering the ethical norms in the laboratory setting. Russow advocates for an “ethics of caring” as engendered by human-animal interactions to supplement “impartial” theories such as utilitarianism and deontological ones. Her concerns for more a nuanced animal ethics have been echoed most recently by essays in Bovenkerk and Keulartz's (2016) *Animal Ethics in the Age of Humans: Blurring Boundaries in Human-animal Relationships*. Philosophers and other scholars are invested now in studying not just the ethics of animal welfare but also why we consider the death or intentional termination of an individual morally concerning (e.g., Višak and Garner 2015; Meijboom and Stassen 2016). Concerns for the ethical treatment of animals have also led to revisions of professional codes of conduct and greater interest in animals by veterinary and animal science organizations all across the world (e.g., Lord et al. 2017; Phillips et al. 2012; Heleski et al. 2004, 2005). Animal scientist, David Fraser in *Animal Ethics and Animal Welfare Science: Bridging the Two Cultures* (1999) and again in *Understanding Animal Welfare: The Science in its Cultural Context* (2008b) issued a challenge to both the scientific and animal ethics communities. For the former, he argued for greater awareness and self-reflection of and engagement with the norms and values that guide their research on animal cognition, welfare, and behavior. For the latter, he emphasized the need for ethicists and philosophers to be informed about the circumstances of animal husbandry and use and to grapple with the on-the-ground constraints of animal scientists and veterinarians so that ethical recommendations that are made can lead to practical solutions. Philosopher, Paul Thompson has encouraged philosophers to transcend traditional forms of “humane moralisms” and embrace collaborations at the intersectionality of philosophy and science so that those working in various animal industries can exact effective guidance from the relevant academic research (2004).

In contemporary Western society, an anthropocentric outlook is seemingly pretty entrenched.

Human beings are inclined to give themselves priority over members of other species. Those still resistant to the idea that animals matter morally in their own right and should not be given membership in the moral community can be considered “exclusivists” or “human exceptionalists.” They exclude animals from the moral community because animals do not bear certain moral qualities that are deemed morally significant. Historically, influential philosopher and the professed “father of modern philosophy and modern natural science,” Rene Descartes (Descartes 1637/1988), for example, argued that animals were limited in their hardwiring. While they are capable of “sensation,” and possessed memory, perception, fear, joy, and hunger, Descartes argued that these experiences were not conscious in the relevant sense. A leading exponent of the mechanistic view that emerged after the middle ages, Descartes argued that only human beings were “thinking beings.” Animals or “brutes,” Descartes contended, failed to count morally since they lacked human language and rationality. Based on these omissions, Descartes argued that they could be subjects of experimentation and dissection. By his lights, animals are but nature’s complex automata akin to biological robots. They do not demonstrate actions that suggest inner thinking. Pierre Gassendi, a contemporary of Descartes’ who was priest and logician, focused not on reason but on animals’ perceptive abilities and ability to suffer. He went on to write that “There is no pretence in saying that any right has been granted to us by [the Moral Law] to kill any of those animals which are not destructive or pernicious to the human race.” Contra Descartes, Gassendi called for compassion towards animals.

Another influential exclusivist is philosopher Immanuel Kant (1724–1804). Kant denied that human beings had direct duties to animals (only duties *about* them) for they lacked higher-order cognitive capacities and thus, *moral personhood*. In his *Lectures on Ethics* (1963), Kant argued that we should treat animals well since treating animals inhumanely could likely lead to mistreatment of other human beings and was a sign of weak character. “If a man shoots his dog because the animal is no longer capable of service, he does

not fail in his duty to the dog, for the dog cannot judge, but his act is inhuman and damages in himself that humanity which it is his duty to show towards mankind. If he is not to stifle his human feelings, he must practice kindness towards animals, for he who is cruel to animals becomes hard also in his dealings with men” ([1784–5] 1997, p. 212).

These sentiments found in Descartes and Kant still prevail in some circles in more nuanced instantiations. Christine Korsgaard, for example, argues that animals while (unlike Kant) proper objects of moral consideration do not possess a reflective mind and thus are not sources of normativity (i.e., cannot convert their desires to reasons for moral actions, for the lack both “practical” and moral identities (Korsgaard 1996, 2007, 2015)).

A variant of exclusivism today is contractarianism (see also Carruthers 1992; Rowlands 2011). Canadian philosopher Jan Narveson is a main exponent of this approach. According to Narveson (1983) and following the tradition of Thomas Hobbes, morality is a function of certain conventions or contracts between members of a political community, i.e., contractors of comparable abilities or political-ethical “powers.” Animals lack certain morally valuable qualities such as metacognitive capacities (e.g., linguistic capabilities, or the ability to form and give reasons) that disqualify them from being able to make, keep, and understand the implications of promises, the basis of contracts. For Narveson, it would be foolish to make promises with “lower animals” since they cannot reciprocate morally for they are fixated on mere conscious activities – responding to and satisfying immediate perceptions and desires, respectively. Human contractors may have indirect obligations to animals by way of how animals stand to other human contractors. This relational link gives animals indirect moral significance but it still does not generate direct concern for animals’ welfare, suffering, or dignity.

In contrast to proponents of human exceptionalism, inclusivists challenge the underlying premise that only and all human beings matter morally. They also call into question the rational basis of personhood since not all human beings

are rational. They offer other criteria for moral considerability. Two animal ethics philosophers who have gained prominence as inclusivists are Peter Singer and the late Tom Regan. Both philosophers argued that animals merit direct moral consideration in their own right. Much of recent philosophical animal ethics, since the 1980s at least, has been framed (i.e., the “animal welfare-right” debate) by Singer and Regan.

Both Singer and Regan challenge the view that all and only human beings have moral status by raising concerns regarding “marginal case” (an unfortunate term in the literature) human beings who lack properties associated with human exceptionalism. Human infants and certain mentally challenged human beings would be excluded from being the recipients of direct moral respect in their own right if reason, rationality, or higher order cognition became predominant moral status defining properties. Singer seeks to secure higher levels of protection for nonhuman animals who can suffer by reforming current systems of animal use. Regan, on the other hand, sought to overcome the view that human persons deserve greater priority over animals simply because they are human.

Singer’s ethical commitment is rooted in the moral theory utilitarianism. Utilitarians seek to bring about the best outcomes for all the relevant parties. Singer extends coverage to all *sentient* animals. Singer’s view is informed by utilitarian progenitor Jeremy Bentham who argued that there is no good reason to exclude animals from the group of constituents that could be harmed morally (1789, *Introduction to the Principles of Morals and Legislation*). While Bentham focused on pain and pleasure, Singer emphasizes preference satisfaction and frustration. As a preference utilitarian, Singer (following in Bentham’s footsteps) contends that, “[t]here can be no moral justification for regarding the pain (or pleasure) that animals feel as less important than the same amount of pain (or pleasure) felt by humans” (Singer 1990, 1975). On Singer’s view, moral agents ought to maximize preference satisfaction (including the conscious desires, projects, and goals of agricultural and research animals) or minimize preference frustration. We should limit

harms to sentient beings who can conceive of their own futures and have the capacity for forward looking desire satisfaction.

Singer is an outspoken critique of *speciesism*, a concept coined by Richard Ryder (1971) (see Waldau 2001) which translates to the discrimination against animals (or privileging human interests) *merely* on the basis of species identity. Speciesism is as indefensible as racism or sexism (Singer 1979a). There is a slight nuance to Singer’s view in that for some animals (those that may just have an immediate interest in suffering avoidance but not a future directed interest in continued existence), killing does not constitute a moral harm in utilitarian terms if they are euthanized painlessly, replaced, and overall welfare is preserved (Singer 1979b, 2011). Under the current forms of animal use, Singer concludes that we ought to strive to adopt moral vegetarians or minimize use of animals in medical research (Singer 1990), since the benefits of current animal use to humans and animals do not justify the harms done to animals. Singer’s utilitarian argument allows some degree of moral toleration of animal use, since humans have a wider range of interests that animals do not, and if the practice promotes happy lives and painless deaths for the animals.

While Singer’s criterion, sentience, has been instructive in making moral claims on us, it has been criticized for being too simplistic and failing to recognize important moral differences in the quality and richness of life between humans and animals (e.g., moral culpability, reciprocity, and self-respect). Singer’s initial call to boycott industries of animal agriculture and biomedical research has not brought lasting changes. Other strategies have proven to be more effective in the long run to inform change, such as active citizen-producer participation in public policy making, engagement with certain animal industries and animal science communities, and consumer pressure and citizen ballot initiatives (Appleby 1999). Singer has also been criticized for failing to acknowledge structural impediments (e.g., market and cultural forces, willingness to pay, and operating costs) that hinder reform of animal industries and the adoption of higher standards of care and

welfare practices by caregivers of animals such as farmers (Stuart et al. 2013; Fraser 2001).

Tom Regan, in contrast to Singer's utilitarianism, defends animals as moral rights bearers as he launches against the instrumentalization or commodification of animals as mere resources. According to Regan, "...animals are treated routinely, systematically as if their value were reducible to their usefulness to others, they are routinely, systematically treated with a lack of respect, and thus are their rights routinely, systematically violated" (Regan 1985, p. 24). As a non-consequentialist, Regan argued that the basis of making ethical judgments should be to ensure that we treat others with dignity and respect regardless of the outcome (e.g., if it would maximize utility to harm them). Animals, in the spirit of Kant's rational personhood argument, should be treated as ends in themselves. Direct moral consideration should be afforded to all "subjects-of-a-life" (SOL) and not just to human persons or moral agents. According to Regan, some animals are subjects-of-a-life (SOL), have inherent worth, and deserve moral respect/have rights (Regan 1983). Even if the good outcomes outweigh the badness, Regan contends that it is unethical to exploit animals in order to benefit others. SOL "possess an integrated inner life," i.e., that there is something to be that individual that includes having desires, a sense of the future, expectations and goals, and mental continuity that grounds the bases of interspecies respect. Regan's abolitionist view regarding animal use is nuanced. He offers the mini-ride principle (where comparable harms are concerned, we ought to override the protected interests of the fewest number of individuals) and the worst-off principle (where noncomparable harms are concerned, we ought to avoid injuring the individual who will be worse-off) as attempts to arbitrate how moral claims made against moral agents should be assessed or to adjudicate conflicting ones.

Russow (1988) criticized Regan's definition of subjects-of-a-life for its lack of specificity and usefulness as a moral category. Anthony (2009) has argued that Regan's strong animal rights, which aims to emphasize species similarities and egalitarianism, puts animals into an amorphous

group with the same moral identity and does not appreciate the uniqueness and diversity of capacities in the animal kingdom that make for different bases for moral treatment.

In recent years, Christine Korsgaard has developed a different Kantian cum rights-based alternative to Regan's subjects-of-a-life approach. She acknowledges that "we have obligations to animals" and that their pain is "not a trivial fact" (1996). She argues that human beings ought to respect the dignity of animals. The basis of human duties towards animals on Korsgaard's (2011) view is recognition of their behavioral drives or natural inclinations. This view, which draws from Nussbaum's (2006) notion of capacities and Rollin's (1981) concept of *telos*, deemphasizes human characteristics as the basis of moral significance of animals' moral claims on human beings. Instead, they give ethical priority to natural species prerogatives, diminishing the significance of countervailing elements in the process. Under Nussbaum's capabilities approach (an extension of her work on human rights), certain capacities of animals define their agency or good of their own, and delineate the contours of their moral claims on moral agents. "[T]here is waste and tragedy when a living [nonhuman animal] has the innate, or 'basic' capacity for some functions that are evaluated as important and good, but never gets the opportunity to perform those functions" (Nussbaum 2004, p. 305). Further, as a matter of justice we should be concerned with the quality of an animal's life, its dignity and free movement, and affiliations with conspecifics (Nussbaum 2006). More pointedly, "The general aim of the capabilities approach in charting political principles to shape the human-animal relationship would be ... that no animal should be cut off from the chance at a flourishing life and that all animals should enjoy certain positive opportunities to flourish. With due respect for a world that contains many forms of life, we attend with ethical concern to each characteristic type of flourishing and strive that it not be cut off or fruitless... Human beings affect animals' opportunities for flourishing, pervasively... Respect for other species' opportunities for flourishing suggests [a more]... robust, positive political

commitment to the protection of animals ...” (Nussbaum 2004, p. 307).

While many philosophy and ethics courses have employed the philosophies of Singer and Regan (i.e., the animal welfare-rights debate) to showcase the theoretically important aspects of traditional ethical theories like utilitarianism and rights-based approaches, of late, more nuanced approaches to improving the lot for animals have gained currency. Many of these approaches are informed by empirical details involving animals’ capacities (Rollin 1995a; Nussbaum 2006; Varner 2012; Thompson 2015) and are responsive to problems faced by those working with animals on a daily basis (Korthals 2016). Many of these approaches, generally speaking, reflect the view that our treatment of animals should be grounded both in empirical fact and reflect normative ideals or human virtues regarding interspecies equity and stewardship. They aspire to determine respectful practices that are based on a more intimate understanding of animals’ points of views or animal-based measures and mutual dependencies between the species (Bovenkerk and Keulartz 2016). Examples of these proponents of these approaches include relational (feminist) theorists, Mary Midgley (1983) and Josephine Donavon and Carol Adams (2007), proponents of the ethics of care approach, and Bernard Rollin (1995a) (communitarianism).

On the relational or ethics of care approach, the relationships we have with others help to carve out our responsibilities to “the other.” Thus, our actual fellowship with animals forms the basis of our care, compassion, respect, and empathy towards members of our mixed communities (Midgley 1983; Gruen 2015). Elizabeth Anderson has argued that, “Moral considerability is not an intrinsic property of any creature, nor is it supervenient on only its intrinsic properties, such as its capacities. It depends, deeply, on the kind of relations they can have with us” (Anderson 2004, p. 289).

Enduring bonds can be formed between humans and animals and these relationships acquire moral significance (Donovan and Adams 2007; Anthony 2003; Russow 1999). This view recognizes that moral obligations are necessarily

multifactorial. That is, our moral obligations are determined by different kinds and strengths of needs, the kinds and contents of interests that are associated with the one cared for, and the context (e.g., urgency, preferences, clinical indications) of both caregiver and recipient of care. Concerns related to this view mainly have to do with the notion of community and strength of the bond between human beings and animals. Animals regarded as “pests” or which do not belong to a “charismatic” species or those with whom we may not have a strong emotional attachment may not show up on our moral radars as deserving of moral concern and hence require supplemental protections.

On communitarianism or the social ethics approach à la Bernard Rollin, technology and economics have usurped the traditional prudential relationship between humans and animals that underscored a kind of interspecific contract: “If one’s animals did not fare well, then you did not either.” The commodification of animals is correlated to their invisibility in our communities and limited exposure to them, e.g., in terms of their final form as packaged protein at grocery stores or delivered vittles. For many of us, animals are “absent referents” (Adams 2000). Rollin’s view focuses on meeting the evolutionarily inherited species endowments or adaptations of farmed animals, i.e., their *teli* or distinctive natures. *Telos* is, “a nature, a function, a set of activities intrinsic to [an individual of a particular species], evolutionarily determined and genetically imprinted.” For those of us who interact with animals, we know that “[they] have natures – the pigness of the pig, the cowness of the cow, ‘fish gotta swim, birds gotta fly’ – which are essential to their well-being. Common sense tells us that animals who are built to move need to move to feel good; there is no point in trying to prove that they are fine if kept immobile.” Being respectful to animals is tantamount to ensuring that animals have access to natural elements in their environment so that they can express their evolutionarily shaped species endowments and adaptations (1995a). Rollin’s emphasis on according intrinsic value to evolutionarily established species typical “natures” or behaviors has been critiqued for

being ambiguous and unscientific. Also, in the wake of advances in modern molecular biology, e.g., Dolly the sheep cloned from an adult somatic cell or the AquaAdvantage salmon, there is some question over just what weight “*telos*” bears morally if we can enhance an individual animal’s welfare by transcending its “nature” through genetic modification or other forms of technological enhancements. Rollin has attempted to address this issue by employing the conservation of welfare principle (Rollin 1995b). By his lights, genetic alteration is morally problematic if it would worsen an animal’s well-being relative to unaltered fellow creatures or if the individual in question would have enjoyed a better life without the intervention.

These approaches highlight a plethora of ways we experience animals morally and provide additional arguments to challenge poor or disrespectful treatment of animals. When we consider our relatedness to animals as morally significant, we are able to acknowledge the impact of the moral claims made on us (Gruen 2015). Treating animals poorly, for example, may not be a function of violating rights they possess or a failure to attain an optimistic balance of good outcomes over bad ones. Instead, it may be a function of insensitivity, lack of compassion, and immaturity towards members of the moral community. The relational and communitarian views bring to light virtues and qualities of character that align with attitudes of compassion and mindfulness that underlie our relationship with animals and alternative ways of seeing animals. This is echoed by Hursthouse, a virtue theorist:

“I began to see [my views] that related to my conception of flesh-foods as unnecessary, greedy, self-indulgent, childish, my attitude to shopping and cooking in order to produce lavish dinner parties as parochial, gross, even dissolute. I saw my interest and delight in nature programmes about the lives of animals on television and my enjoyment of meat as side by side at odds with one another...Without thinking animals had rights, I began to see both the wild ones and the ones we usually eat as having lives of their own, which they should be left to enjoy. And so I changed. My perception of the moral landscape and where I and

the other animals were situated in it shifted” (Hursthouse 2000, pp. 165–166).

These approaches also highlight the importance of empirical evidence in revealing how animals actually are. Animal scientists and cognitive ethologists have an important role to play in filling in the actual relationship between species-specific behaviors and how animals’ interests are frustrated or rewarded when they are actualized. For example, it is unclear that animals are harmed morally or have their “rights” violated in every instance in which their natures or species-specific behaviors are frustrated. Animals may have other adaptive capacities that can offset momentary frustration or discomfort (Fraser et al. 1997). Here, those in the empirical sciences can help philosophers understand the links between frustrated behaviors or psychological distress and diminished welfare, and good welfare and the expression of “natural” behaviors as well as reveal the relationship between the behaviors’ evolutionary and physiological antecedents and their impacts on animals’ welfare (Fraser 2008a).

As philosophical animal ethics advances, philosophers and scientists alike are increasingly interested in transcending the seemingly inherent individualism that has plagued philosophical animal ethics (Swart 2016; Dubois and Fraser 2013; Fraser 2010). Rather than focus on the impact of intrinsic or innate properties of individual nonhumans as the basis of their moral considerability, improving arguments regarding the moral recognition and value of species, (including conservation or management strategies and the permissibility of altering the genome) will be an important frontier in human-animal relationships.

## **Beyond Animal Ethics: Investigations into the Inner Lives of Animals**

Although a lot of attention has been given to the ethical shape of our relationship to animals in the philosophical literature, philosophers have also been interested in the capacities of animals, such as their inner lives as its own field of inquiry. Philosophers working on animal issues, for their part, have availed themselves of the empirical

research in animal consciousness, language, memory, emotion, behavior, and cognition in exploring animals' minds. Research in the philosophy of mind or consciousness studies, while connected to work in animal ethics, is also intriguing in itself. Philosophers of mind are interested in animal consciousness and cognition, the nature of sentience, animal emotions, and other phenomenological experiences or "qualia," i.e., the something it is like to be it, for example, is there something it is "like to be a bat?" (Nagel 1974). Noted philosophers of mind, Tom Nagel (1974) and Peter Carruthers (1989) have been interested in "theories of mind" or the inner lives of animals and have spawned much interest in extending metaphysical approaches and categories of mind-brain to animals, including paradoxes of consciousness, psychopathologies, and higher-order thought processes (Gennaro 2009). Furthering the ground that Descartes laid, Carruthers (1989) initially denied that animals possessed experiences that are conscious because they lacked the requisite hardwiring found in humans. In a version of Descartes "biological automata," Carruthers argued that animals are on "autopilot" since they lack proposition language, a prerequisite for having beliefs and desires. Carruthers also echoes Donald Davidson (1982) here who argued for the necessity of propositional language in higher order capacities like having future-oriented beliefs and desires, and being able to plan and execute certain projects that did not hinge on gratifying immediate affective states (see also Gennaro 2004; Robinson 1997). Carruthers has since changed his view (2006), citing that different physiology and anatomy from that possessed by human beings can also give rise to conscious phenomenal experiences. David DeGrazia, (1996) in *Taking Animals Seriously: Mental Life and Moral Status*, makes the vivid case for "animal mentation" and its connection to attributions of moral considerability to animals.

Many of the philosophers identified above like Singer and Regan who work in animal ethics rely on factual or empirical details about animals' mind to either justify or debunk human exceptionalism (Andrews and Beck 2017; Varner 2012; Lurz 2011; Beauchamp and Frey 2011). Animal

scientists, for example, animal welfarists and cognitive ethologists (e.g., Duncan 2006; Weary et al. 2017; Dawkins 1993), have and continue to provide important evidence regarding the mentality of animals and their capacities. Knowing about consciousness and capacities for pain and suffering intersects with real-world concerns such as best practices for performing euthanasia (<https://www.avma.org/KB/Policies/Documents/euthanasia.pdf>), or for minimizing unpleasant effects on research animals (<https://grants.nih.gov/grants/olaw/guide-for-the-care-and-use-of-laboratory-animals.pdf>) that veterinarians and scientists are also invested in. Animal scientists either assessing or working on improving the quality of lives of animals through frameworks like the Five Freedoms (Brambell 1965) or Fraser's Three Domains model of experiential and physiological welfare and opportunities to express species typical behaviors (Fraser 2008b; Fraser et al. 1997) also appeal to the inner lives of animals to promote better quality of life for animals. Philosophers like Singer and Varner appeal to evidence regarding which animals are able to experience states of satisfaction and frustration in making utilitarian style moral arguments. Regan style ethical arguments regarding subjecthood and mental complexity (1983) depend on evidence of biographical existence and future-oriented desires. Rollin is concerned if animals are temporally fixed in the present (1998). New frontiers in animal ethics, like fish cognition and welfare (Allen 2013; Braithwaite 2013) and the impacts of emerging (bio or neuro) technological manipulations on animals (Takala and Häyry 2014), also rely on the latest science regarding animal minds. Interdisciplinary collaboration is thus essential to curtail concern for anthropomorphism, the projection of human qualities onto nonhuman entities (Daston and Mitman 2005; Bekoff and Allen 1997; Fisher 1990).

Beyond matters of ethics or normativity, there is much opportunity for cross-pollination between cognitive ethologist and animal scientist and philosophers to probe together and carve out new research trajectories regarding the inner lives of animals (Andrews 2015). The work of

philosophers, like Allen and Bekoff (1997), Varner (2012), and Lurz (2011), have shaped the way animal scientists (e.g., Braithwaite 2010; Ian Duncan 2006) and cognitive ethologists (Griffin 1976) think about the mental capacities of animals and vice versa. Animal scientists, ethologists, and cognitive and neuroscientists have already helped to provide evidence supporting higher cognitive state in animals including higher order capacities for planning and execution and emotions (Panksepp 2005). Birds, fish, and other non-mammalians have been shown to have the capacity to learn from past experiences (Allen 2013; Braithwaite 2010; Allen and Fortin 2013). Beyond showing that pain, suffering and positive affective states are widespread throughout the animal kingdom; recent scientific evidence is highly suggestive that human beings no longer have a monopoly on “theory of mind,” higher order thought, and that episodic memory, self-consciousness, joy, empathy, desires and beliefs about the(ir) future, and fulfilling projects or “mindreading” others’ intentions or the capacity for deception are also distributed in other species (Gennaro 2016; Varner 2012; Bekoff 2007).

New opportunities are afoot (e.g., Buller 2014) to broaden existing metaphysical views (Dennett 1996) regarding the richness of animal minds especially, as greater attention is devoted to resolving debates regarding what morally relevant capacities of animals should be taken into account in our treatment of them and in our quest to improve the welfare of other species in our sphere of influence. Rethinking the morality of human-animal relationships and metaphysical and scientific connections regarding animal minds will not only benefit animals in the long run but also afford us the opportunity to reflect on our own humanity and its trajectory (Gruen 2015; Bradshaw 2009).

## Conclusion: Ethics, Animals, and Science

Ethical inquiry into the philosophical bases of respectful human-animal interactions and relationships provides a systematic way of examining and assessing the merits of different viewpoints

and theories regarding these interactions in a structured way. This process appears to be the cornerstone of the 1985 US Animal Welfare Act and the basis of the 1986 establishment of IACUCs in the wake of the Silver Springs macaque incident. Ethical and philosophical inquiry can be critical in probing the attitudes, prejudices, misunderstanding, biases, and assumptions that motivate how we should regard and treat animals. They can help us reveal and gauge our attitudes regarding animals and highlight possible implications of different perspectives that influence public and disciplinary attitudes on human duties towards animals (Appleby and Sandøe 2002). The work of ethicists and philosophers to interpret our ethical judgments and values about animals and how the latter should influence practice and policy can reveal central points of tension and internal inconsistencies within the perspectives we hold, and remind us that the moral considerability of animals and the significance of their interests should be balanced alongside other relevant and vital projects that deserve our critical attention. While respect and proper treatment of animals is a weighty norm, our moral lives also consist of other duties we have towards ourselves, others, and the natural world (Bovenkerk and Keulartz 2016; Jamieson 1998). Thus, in thinking ethically about whether and how to use animals, due consideration should be given to when our duties to animals may be overridden by other important moral or practical concerns. If our moral judgments regarding human-animal interactions are to have any weight at all, they should be backed by the best of reasons. Here, they ought to be the result of careful reflection in which we have arrived at good reasons for accepting them. These reasons should be in a format that can be recognized as action guiding by any other conscientious and reasoning person.

The dominant debate in philosophical animal ethics for the last half decade or so has assumed the form of discovering the terms of membership of the moral community and then debating whether that membership affords full or equitable moral significance and protection to moral agents and subjects alike (Garner 2013). Today, philosophers

recognize that there are multiple ways in which ethical norms and concepts exert a pull on our reason and emotions, and good reasons for justifying healthy human-animal interactions requires integrating philosophical work on animal ethics with research by animal scientists and others dedicated to improving the welfare of animals. Objective norms and standards for respectful treatment of animals need not be relative to cultural or individual whim. Important gains in information about what animals need and are feeling or thinking either by direct or indirect means have been made that have enhanced our experiences, moral imagination, and sensitivity regarding what matters to various animals. A fairly solid body of science is available now about the capacities of animals beyond experiences such as fear, pain, and frustration. Gaps in knowledge remain on states of pleasure such as joy and happiness in animals and just where during an individual's ontogenesis or during the evolutionary development and history of a species morally significant capacities like sentience, self-consciousness, and other higher order thoughts emerge (Gennaro 2016; Bovenkerk and Keulartz 2016; Boly et al. 2013).

Animal and cognitive science have contributed immensely to ethical inquiry into the nature of our obligations to animals. A deeper appreciation of phylogenesis, biological functioning, anatomical similarity, and "animal mentation" have all contributed to a better understanding of how animals can be benefited and harmed as a result of human actions and omissions. Ethical inquiry coupled with philosophical and scientific engagement on the viewpoint of animals will continue to illuminate how to improve human-animal interactions and animal welfare (Fraser 2009; Thompson 2004). Opportunities for improvement lie in the ways in which we handle, house, and manage animals (individually or at the group level), and what different philosophical conceptions and arguments regarding their moral status and measurements of animal welfare mean to the animals themselves.

Partnership between ethics and science is vital in helping us discover which animals are capable of experiencing morally relevant states such as pain or self-consciousness. As moral agents, we

are obliged to take all morally relevant features into account in our treatment of animals, including their minds, natures, and experiential and physiological welfare. Just how we should take these features into account falls to both members of the philosophical and scientific communities. Weighing probabilities of harm and benefits and relative weight given to other features of our moral lives is a shared project. Finding ways to match concerns about why animals matter with how they matter in light of what threatens to cause animals harm given the capacities they possess is a shared project.

## Ethogram

Michael J. Renner  
Drake University, Des Moines, IA, USA

### Synonyms

[Behavior catalogue](#)

### Definition

A descriptive inventory or catalogue of all behaviors used by a particular species of animal.

### Introduction

One of the fundamental issues in any branch of science is how to measure the components (objects, entities, and events) studied by that branch of science. The discoveries in a branch of science can be no better than the quality of the measurements used in that field. In the study of animal behavior and cognition, the events that are studied are the behaviors of animals; the components of animal behavior are measured according to an intellectual construct called an *ethogram*.

The construct of an ethogram originated in the field of ethology in the 1930s, derived from the Greek *ethos*, meaning “nature” or “disposition,” and *gram*, meaning “writing or drawing.” The term is now a common tool in all areas of the study of animal behavior, regardless of theoretical orientation. In its simplest form, an ethogram is an exhaustive list of all the behaviors exhibited by individuals belonging to a particular species. Each behavior is operationally defined, meaning that it is defined by the criteria that must be satisfied before that behavior can be said to have occurred.

### Ethogram Requirements

The basic requirements for the development of an ethogram are that it must include an exhaustive

list of behaviors, and those behaviors must be defined in ways that are mutually exclusive. The term exhaustive means that anything the animal might possibly do – its entire behavioral repertoire – can be classified somewhere in the catalog; mutual exclusivity means that no action can simultaneously meet the criteria for more than one of the behaviors represented in the list. This requirement is logically necessary, so that no matter what behavior occurs, there is one and only one way to classify that behavior.

The term ethogram was originally applied only to behavioral catalogs that were believed to be comprehensive; over time, however, the term has come to be used to describe more limited behavior catalogs. For example, a particular investigator may have been primarily interested in courtship behavior; such an investigator might, through extensive study and detailed analysis, develop a complete and nuanced list of behaviors for only those behaviors found in the particular context of courtship and reproduction. Animals do, however, engage in behaviors other than courtship and reproduction. The requirement that the catalog be comprehensive could be satisfied in this situation by the inclusion of a broad category (e.g., “other behavior”) into which all noncourtship-related behaviors would be classified. The requirement that all behaviors be classifiable somewhere in the catalog is satisfied, without the investment of time and resources required to develop detailed operational definitions for behaviors that are not of interest in this particular context.

Before the ready availability of video recording and electronic recordkeeping, it was necessary to conduct behavioral observation in real time; this circumstance dictated that behavioral classification systems be straightforward even sometimes to the point of oversimplification. The availability of technologies that allow the examination of behavior in slow motion or stop-action, as well as observing the same instance multiple times, has permitted the collection of data concerning complex streams of events, which has in turn permitted the development of richer,

more complex systems (e.g., Renner and Seltzer 1991).

Video capture and analysis technologies have made it possible for this concept of mutual exclusivity to evolve, recognizing the existence of multiple semi-overlapping behavior streams in an individual animal. These behavior streams are coded in ways that can be separated for some analyses and recombined for others, allowing the coding to capture the layering of different component behaviors that occurs in nature (Renner and Seltzer 1994).

To illustrate, behaviors can occur as events (i.e., meaning that they are of very brief duration, or punctate, functionally occurring at a single point in time, such as a canine bark) or states (having an indefinite duration, such as lying down). Although it is certainly possible to construct a coding system that includes “barking while lying down” as a behavior distinct from “sneezing while lying down” and “lying down without making noise,” it is simpler to understand an ongoing state of “lying down” that may or may not have embedded events such as “bark” or “sneeze.”

Nevertheless, for ethogram to successfully describe the behavior of a species, any action that can be displayed by any individual member of that species must fit into one, and only one, category in the ethogram.

### Defining Behavior

Two approaches to defining behaviors (and through definition, measurement) are always in dynamic tension. The first approach is to determine what behaviors can be easily and reliably quantified and then to measure those behaviors, with a likely eventual goal of assigning functional significance to the behavior patterns detected in this way. A behavior may be defined in strictly physical terms by describing the positions and movements of specific body parts over time (c.f., Eshkol and Wachman 1958). This approach is often useful when the function of the target behavior is poorly understood or disputed. Because such definitions are based on objectively observable phenomena, they require relatively little context-specific knowledge of the species' habits and

ecology. For example, one could define “sniffing an object” in a quadruped as follows:

Interaction with an object that is anterior to the plane perpendicular to the spinal column at the level of the animal's ears, and within a sphere centered on the tip of the animal's nose with a radius of the distance between the tip of the nose to the plane of the ears.

This definition, although sterile, does not require the observer to make judgments about the animal's intent.

The second approach is to determine what is interesting or important on theoretical or conceptual grounds, and then to attempt to develop methods to measure, however imprecisely, those behaviors. This approach is often accompanied by the assertion or assumption that successive iterations of the measurement technique will produce improved precision. One example of this approach is often called a functional definition, which defines a behavior by observing the outcome of the interaction between the animal and its environment. One might define eating as follows:

Interaction between an animal's mouth and some object or substance that results in the ingestion of the object or substance.

This definition makes no attempt to specify whether or how the object or substance is chewed, only that interaction occurs with the net outcome of ingestion. More generally, functional definitions allow for variation in specific motor patterns, grouping behaviors together if they achieve a common result.

### Ethogram Uses

Once a usable ethogram exists for a particular species, it becomes possible to empirically determine the time budget for that species. A time budget reports how individuals of the species typically allocate time among possible behaviors. Although there is considerable interindividual variability in behavior within a species, as well as circadian and seasonal changes in behavior patterns, the behaviors used to solve the basic problems of life (e.g., finding food, shelter, mates, etc.) do not vary, and so these variations likely occur as deviations from a characteristic or default time budget for a species.

Such a time budget can also serve as a useful baseline reference in evaluating the behavior of animals under captive management. The absence of opportunity to exhibit particular species-typical behaviors reflected in the ethogram can lead to stress, which may result in, or be indicated by, the presence of stereotypic behavior. Similarly, captive animal management standards now require a program of environmental enrichment, the implied goals for which include the absence of abnormal behavior (i.e., stereotypies) and the behavioral expression of the full ethogram for that species (Renner et al. 2000; Renner and Plebani Lussier 2002). A known time budget for is a powerful reference point in such work.

An ethogram is conceptualized as concerning a single animal's behavior, but it is possible that the catalog for an individual's behavior may well include interactions with one or more other individuals. Social behaviors can include those in which the subject animal is the agent (e.g., a facial grimace directed toward a conspecific), the object or recipient (e.g., defensive behaviors), or one of an obligatory pair (e.g., one actor in a mutual courtship display sequence, where both animals must act for the sequence to exist).

### Observational Methods

An ethogram can be used as the basis for recording behavior through any of several observational methods. The choice of method dictates some of the characteristics of the data that can be collected, and constrains the types of generalizations and inferences that can be drawn from the data (Altmann 1974).

Instantaneous sampling is the practice of classifying which behavior is occurring a single point in time; this is commonly applied periodically (e.g., making one observation per minute). This method is akin to capturing a series of still images; it produces data that are relatively easy to analyze, but this type of data tends to underrepresent short-duration behaviors (i.e., events) and thereby overrepresent behaviors that have variable duration (i.e., states).

An alternative is one-zero sampling, in which the observation period is divided into a series of time periods, which are sometimes referred to as

time bins. The observer records which behaviors from the ethogram occur during each of these time periods; within each time period each behavior is classified as present (1) or absent (0). There is no attempting to record either the duration of any behavior or the number of times that a particular behavior occurs during the time period. One-zero sampling captures short-duration behaviors (i.e., events) more effectively than instantaneous sampling. The tradeoff, however, is that multiple behaviors can occur within a single time period; information about the durations and sequences of behaviors is lost.

The most complete record of behavior for a defined period of time is known as continuous recording, in which every behavior of an individual is recorded and its duration timed. This approach captures states, events, and order of behaviors. However, it is complex and difficult or impossible to accomplish with precision in real time. It requires highly trained observers, is more susceptible to error, and is far more labor-intensive than other methods because it generally requires analysis of video records after the fact.

### Measuring the Behavior of Multiple Individuals

There are two methods available for measuring the behavior of animals living in groups. Focal animal sampling involves recording the behavior of an identified individual from the group over a period of time. To represent the behavior of the group, multiple observers can be employed during a single time period, or a single observer can observe different individual animals at different times. Scan sampling involves surveying the entire group at a point in time in order to count the number of individuals that are engaged in each of the behaviors from the ethogram; these instantaneous samples are repeated at defined intervals. Such a survey of the group provides what amounts to a behavioral census; over time, this type of data this reflects the distribution of behaviors across the entire group.

### Instrumentation and Reliability

Some behaviors, although they may not be amenable to measurement by automated methods, can

be measured by proxy measures that can be automated. For most ethological study, however; the application of human judgment is necessary to properly categorize behavior. Therefore, detailed study of animal behavior requires human observers and remains highly labor intensive. As scientific models of behavior become more sophisticated, and as technologies advance (in particular pattern-recognition, image analysis, and the identification of physical events that can serve as reliable proxies for behaviors or sequences), it is likely that more types of behavior observation will become amenable to automation.

The measurement of behavior through observation raises the question of whether the judgments of different observers are equivalent. This is addressed in ethology through measures of interobserver reliability, using calculated or statistical techniques to assess whether the observations of two or more distinct observers may be treated as interchangeable (Martin and Bateson 2007). In many research programs, a period of apprenticeship or training, followed by extensive evaluation of interobserver reliability and additional training, is required before a new member of the research team begins to collect data that become part of the project's corpus of data.

## Synonyms

[Eukaryotes](#); [Eukaryotic organisms](#)

## Definition

Eukaryota is a major group of organisms, defined by the sophisticated cellular organization. The term “eukaryote” itself means “true nut” or “true kernel” in Greek: the “nut” refers to the nucleus of the eukaryotic cell. The group eukaryota includes all the organisms with a cellular structure that

consists of a nucleus, membrane-bound organelles, and a network of cytoskeleton.

## Introduction

In order to facilitate a systematic study of organisms, the organisms are classified into multiple groups based on their various defining features. The most fundamental level of these classifications is based on the cellular architecture, and at this level all the organisms have been divided into three groups, or domains: Archaea, Bacteria, and Eukaryota. While the bacteria and the archaea are invariably single-celled (unicellular) organisms, the eukaryotes span a vast range: from unicellular protozoans to giant multicellular mammals and trees, and all those in between. In fact, all the organisms visible to the naked eye are eukaryotes, though not all the eukaryotes are visible to the naked eye. This reflects the sheer heterogeneity of the group eukaryota.

## Defining Features of Eukaryota

The eukaryotic organisms can be generally recognized on the basis of the following common features:

**Larger size of cells:** Most conspicuously, the eukaryotic cells are larger than the prokaryotic cells. While the diameter of prokaryotic cells ranges between 1 and 10  $\mu\text{m}$ , the size of eukaryotic cells is a thousand times greater and typically they are between 10 and 100  $\mu\text{m}$  (Cooper and Hausman 2016).

**Multicellularity:** The eukaryotes can be single-celled (i.e., unicellular) or many-celled (i.e., multicellular). Most of the life forms familiar to us are multicellular plants or animals. The life cycle of the multicellular eukaryotes requires several additional features like adhesion of cells together to form tissues, intercellular communication, and differentiation of cells into multiple kinds in order to facilitate division of the labor. Those features are not shared by the unicellular, free-living eukaryotes.

**Presence of membrane-bound intracellular structures:** While the prokaryotes have simple, uncompartimentalized cells in which all the molecular processes take place within the confines of one envelope, the eukaryotic cells have specialized compartments for distinct functions, each one separated by a membrane analogous to the one covering the cell. These intracellular structures are called “organelles.” The most prominent of these structures is the nucleus which houses the genetic material.

Besides the nucleus, the eukaryotic cells have organelles such as mitochondria (for respiration and energy production), Golgi complex, lysosomes, peroxisomes, endoplasmic reticulum, and supporting structures like cytoskeleton.

**Genetic material:** The genetic material of a eukaryotic cell, which is deoxyribonucleic acid (DNA), is folded with the help of histones and some non-histone proteins and gives rise to compact structures, called “chromosomes.”

## Taxonomic Status

According to the three-domain classification system (Woese et al. 1990), all the life forms can be divided into Archaea, Bacteria, and Eukarya domains. This system puts all the eukaryotes within the Eukarya and divides the prokaryotes into Archaea and Bacteria domains.

The credit for proposing the prokaryotic-eukaryotic distinction goes to the book *Titres et Travaux Scientifiques* (1937) by a French marine biologist Edouard Chatton (1883–1947) (Sapp 2005). As the classification system underwent gradual refinement, by 1970 all the living organisms were classified into five kingdoms: Animalia, Plantae, Protista, Fungi, and Monera (Prokaryotae). In this five-kingdom system, the first four encompassed the eukaryotic organisms. In 1977, by comparing the nucleotide sequences of the small subunit of ribosomal RNA (known as 16S rRNA), Carl Woese et al. were able to derive a global molecular phylogeny of cellular organisms. As a consequence of the insights derived through his work, the prokaryotic group was divided into eubacteria and archaea, leading to

the formation of a six-kingdom system. This new system overturned the eukaryote-prokaryote dichotomy and resulted in three most fundamental units, “domains” of life.

The six kingdoms, Archaea, Bacteria, Protista, Fungi, Plantae, and Animalia have been organized under three domains: Archaea, Bacteria, and Eukaryota. According to this system, the kingdoms Protista, Fungi, Plantae, and Animalia fall within Eukaryota. Thus, all the animals, plants, fungi, and protists are the members of Eukaryota group. According to one of the classification schemes, these members of the eukaryota group have been classified into the following clades: Opisthokonta, Amoebozoa, Excavata, Plantae, and “SAR” (Stramenopila, Alveolata, and Rhizaria) (Katz 2012). Opisthokonta, here, includes animals, fungi, and their microbial relatives. Within the “Amoebozoa” clade are included amoebae like *Amoeba proteus*, the slime molds, *Entamoeba histolytica*, and so on. The members of “Excavata” group, for example, the human parasites *Giardia lamblia* and *Trichomonas vaginalis*, are characterized by the occurrence of an excavate groove.

## Cellular Architecture of Eukaryota

The eukaryotic cell is characterized by its sophisticated intracellular organization. Each eukaryotic cell is enveloped by a selectively permeable plasma membrane composed of protein-lipid bilayer. In plants and fungi, there is an additional external layer of a rigid cell wall. Cells connect to and exchange materials with their environment and the neighboring cells through specific adhesions/junctions and transporters embedded in the membrane. Communication of a plant cell with its exterior takes place through numerous plasmodesmata.

The inside of the cell is made up of the fluid, cytosol, and membrane-bound “organelles” (Fig. 1). The membranes enclosing the cell or the organelles have distinct properties which enable them to protect the integrity of its content and facilitate the processes performed by the cell or the organelle. The nature of the membrane may

vary based on the lipid and protein content. Due to the presence of specific receptors, transporters, etc. membranes around different cells or organelles respond differently to their surroundings and help the cell/organelle perform specific functions. For example, while the outer membrane of mitochondria is highly permeable for movement of solutes across it, the internal membrane is very selective and only specific substances can cross it.

## Intracellular Organelles

### Nucleus

Among the intracellular organelles, the nucleus, mitochondria, and chloroplast are double-membrane structures, while the remaining are single-membrane. Nucleus is the largest organelle of a eukaryotic cell. The genetic material of a eukaryotic cell, DNA, is stored inside the nucleus, and processes like replication of DNA, transcription, and RNA processing take place herein. Certain cells, such as mammalian RBCs, lack the nucleus.

The contents of the nucleus are kept isolated from the cytoplasm through a “nuclear envelop” which is made up of double membranes. The exchange of material between the nucleus and the surrounding intracellular material, cytoplasm, happens through large nuclear pore complexes. The space between the outer and inner nuclear membranes extends into the cytoplasm and forms the endoplasmic reticulum. Underneath the inner nuclear membrane, a meshwork of “nuclear lamina” is attached. This lamina is made up of fibrous proteins called “lamins” and provides structural support to the nuclear envelope.

Inside the nucleus, there are a number of different sub-organelles, known as “nuclear bodies” involved in various functions. Nucleolus is one such nuclear body which is associated with ribosomal RNA transcription, processing, and ribosome formation. These nuclear bodies are not membrane-bound structures and are dynamic in nature.

### Mitochondria

The mitochondria are the sites where the breakdown of carbohydrates and fatty acids takes place

E

**Eukaryota, Fig. 1** The cellular organization of a typical eukaryotic cell

to extract energy and ATP is produced through the process of oxidative metabolism. The initial breakdown of glucose, known as glycolysis, occurs in the cytosol. The end product of glycolysis, pyruvate, is transported to mitochondria where it is completely oxidized into  $\text{CO}_2$ . Processes known as citric acid cycle and oxidative phosphorylation, which take place at the mitochondrial matrix and inner membrane, respectively, result in extraction of energy from glucose and its storage in ATP molecules.

### Chloroplasts

Chloroplasts are found in cells of plants and green algae. These are larger and more complex than mitochondria. The primary function of chloroplasts is to carry out photosynthesis and convert  $\text{CO}_2$  to carbohydrates. In addition, these are also sites for synthesis of amino acids, fatty acids, and

lipid constituents of their own membrane. Unlike mitochondria, chloroplasts have an additional third membrane inside the organelle and this membrane, known as “thylakoid,” is the site of ATP generation.

Mitochondria and chloroplasts possess their own genomes. These genomes consist of circular DNA molecules which occur in multiple copies. The organelle genomes encode tRNAs, rRNAs, and some organelle-specific proteins (essentially involved in oxidative phosphorylation). The genomes of chloroplasts are larger and more complex than the mitochondrial genomes.

### Lysosomes

Lysosomes are organelles meant for the digestion of various intracellular and extracellular substances. These contain about 60 different enzymes capable to hydrolyze DNA, RNA, proteins, lipids,

carbohydrates, etc. (Cooper and Hausman 2016). Most of these enzymes act at acidic pH (~5).

#### Peroxisomes

Peroxisomes are the sites of oxidative reactions and many other metabolic processes. These too can replicate by division like the mitochondria and chloroplasts.

#### Cytoskeleton

The shape of the eukaryotic cell is maintained by a scaffold, a skeleton arising out of a network of protein filaments extending throughout the cytoplasm. These filaments are anchored to the cell membrane through a variety of accessory proteins. There are three main types of the protein filaments: (i) microfilaments, made up of actin subunits, (ii) microtubules, made up of tubulin subunits, and (iii) intermediate filaments, made up of various proteins.

The cytoskeleton is a dynamic structure. As per the requirement and the status of the cell, rapid re-organizations of the cytoskeleton enable the cell in shape change, motility, etc. Besides its structural role in maintaining cell shape, and effecting cell motility, the cytoskeleton is also essential in correct positioning of intracellular organelles, and intracellular movement of organelles and other structures. The cytoskeletal protein filaments also play crucial roles in the processes like muscle contraction, and the formation of the spindle apparatus, which separates the chromosomes during mitosis.

#### Flagella

Flagella are long threadlike structures. These facilitate the movement of an organism or cell through liquid medium. The eukaryotic flagellum is a bundle of nine pairs of microtubules surrounding a central pair (the so-called 9 + 2 structure). The eukaryotic flagellum emanates from a microtubule organizing center, or MTOC.

#### Endoplasmic Reticulum

The endoplasmic reticulum, or ER for short, is a complex network of membranes that provides a transport system within the cell. There are two types of endoplasmic reticulum, rough and smooth – the two are contiguous parts of the

same network, distinguished by the presence or absence of ribosomes. The rough ER (studded with ribosomes) is the site of protein formation and transport. The smooth endoplasmic reticulum is the site of lipid formation. The proteins that are destined for organelles like ER, the Golgi apparatus, the plasma membrane, or lysosomes, or for extracellular secretion are synthesized on ribosomes attached to RER, in contrast to other kinds of proteins which are synthesized on free, cytosolic ribosomes. The proteins synthesized on ribosomes on RER are processed within the lumen of the RER and further sorted in the Golgi apparatus, if necessary.

#### Golgi Apparatus

The Golgi apparatus, or Golgi complex, is composed of flattened membrane-enclosed sacs (cisternae) and vesicles outwards to the ER. This structure is responsible for processing, followed by sorting and packaging into vesicles of proteins received from the ER for their transport to their final destinations. The Golgi apparatus is also involved in lipid metabolism, in particular the synthesis of glycolipids and sphingomyelin.

#### Ribosomes

Ribosomes are the sites of protein synthesis. These large complexes of ribosomal RNAs and proteins are composed of two subunits. The eukaryotic ribosomes are larger than the prokaryotic ribosomes and more complex with greater number of proteins and rRNAs. While the bacterial ribosomes are designated as 70S (based on their sedimentation coefficient), the eukaryotic ribosomes are 80S. These 80S macroparticles are made up of 60S and 40S subunits (the subunits of prokaryotic ribosomes are 50S and 30S). Around 46 proteins take part in forming the 60S subunit, along with 28S, 5.8S, and 5S rRNAs. On the other hand, the smaller, 40S subunit is formed by 33 ribosomal proteins and 18S rRNA (Cooper and Hausman 2016).

A key feature of the eukaryotic ribosomes is that a large pool of them is found associated with the endoplasmic reticulum, giving rise to the rough endoplasmic reticulum.

## Vacuoles

In the plant cells, multiple reservoir organelles of large size are present. These are known as “vacuoles.” The vacuoles are involved in digestion of macromolecules and storage of waste products and nutrients.

## Genomic Features

The genomes of eukaryotes are not only larger than prokaryotic genomes, the former are also more complex. The larger size of eukaryotic genomes is not accounted for by a greater number of genes. On the other hand, the eukaryotic genome contains many non-genic regions, like introns, repetitive sequences, regulatory regions, etc. The variations among these regions lead to a huge diversity in genome sizes of eukaryotes. The observation of this discrepancy between number of genes and genome size has been referred to as the “C-value paradox.”

The DNA of eukaryotes is packed inside the nucleus in the form of a DNA-protein complex called “chromatin.” The formation of chromatin reduces the DNA length and facilitates efficient packaging. The major protein constituents of chromatin are histones, with five major types H1, H2A, H2B, H3, and H4. The basic structural unit of chromatin is referred to as “the nucleosome.” The extent to which DNA is condensed to form chromatin varies between different regions and also temporally, resulting in the division of chromatin into euchromatin and heterochromatin regions.

## Origin of Eukaryotes

The oldest sign of eukaryotes is found at least 2.7 billion years ago (Cooper and Hausman 2016). Many features of the eukaryotic cells, including its genome, reveal that the eukaryotes are chimeric, with traits derived both from bacteria and archaea. According to the most widely accepted theory, the eukaryotic cells evolved from a symbiotic association between an archaean host and prokaryotic cells, such as  $\alpha$ -proteobacteria and cyanobacteria. The theory is known as endosymbiosis. The acquisition of aerobic proteobacteria gave rise to

mitochondria of the eukaryotic cells, while the photosynthetic cyanobacteria evolved as the chloroplasts of the green plants and algae. The mitochondria and chloroplasts share features similar to bacteria. These are similar to bacteria in size, have their own circular DNA, and ribosomes similar to bacteria.

The idea of endosymbiosis may be traced to the Russian biologist Constantin Mereschkowsky. Mereschkowsky (1905) was the first to postulate that chloroplasts resemble cyanobacteria and the occurrence of chloroplasts in plant cells was a result of symbiosis between a cyanobacterium and a heterotrophic host. The origin of mitochondria was attributed to an event of endosymbiosis by the French microbiologist Paul Portier (1918). However, the theory of the endosymbiotic origin of cell organelles received serious attention around 1970 by the American microbiologist Lynn Margulis (Margulis 1981). Currently, there are multiple models of the endosymbiosis theory which attempt to explain the various aspects of the eukaryotic origin and evolution (Martin et al. 2015).

## Conclusion

Eukaryota is a vast and diverse group of organisms. It includes all the multicellular animals, plants, fungi, along with unicellular protists. All these members of the eukaryota group are united by their advanced cellular features, which are lacking in bacteria and archaea. The evolution of eukaryotic life involved many innovations like advanced cytoskeleton and multicellularity, which conferred eukaryotes much adaptive advantage leading to their flourishing. The mechanisms which led to such innovations are still matters of debate.

## Eureka Effect

Ragen T. S. McGowan  
Behavior and Welfare Section, Nestlé Purina,  
St. Louis, MO, USA

## Definition

The feeling of positive affect one experiences during problem-solving events where a previously incomprehensible problem suddenly becomes clear.

## Introduction

Imagine someone faced with solving a complicated new problem. This problem-solver tries several strategies to find a solution and then tries again when a new strategy does not work. The individual may experience a bit of frustration or feel as though the task at hand is impossible, until that moment when a solution suddenly comes to mind. A surge of excitement rushes over him/her and in that moment the individual cannot help but exclaim “Yes, that’s it!” This feeling of positive affect specifically as a result of one’s own achievements has been coined the “Eureka Effect.” In human terms, this refers to the feeling one experiences the moment he or she suddenly understands a previously perplexing problem, concept, or task. Evidence at hand suggests that animals may also experience this emotional reaction to their own achievements. Experiments focusing on the intrinsic reinforcing properties of problem-solving and the emotional consequences of responding to challenge for nonhuman animal species are rare, however the handful that are available provide clear evidence in support of the phenomenon. As it is not possible to ask most animals directly how they are feeling during their problem-solving experiences (as one can with humans), it is necessary to use proxy measures to better understand the emotionality around problem-solving. Key studies investigating the Eureka Effect specifically in species ranging from cattle to dogs involve use of a yoked control design to assess whether animals respond emotionally to their own achievements and to tease these emotions out from responses to rewards themselves (e.g., Hagen and Broom 2004; McGowan et al. 2014). These studies have found that animals who master a task in order to control their own access to rewards demonstrate more behavior indicative of excitement than control animals that received the same reward without the opportunity to learn the relationship between the task and gaining access to the reward.

Take for example the study by McGowan et al. (2014) which examined the emotional response to problem-solving in dogs by assigning dogs to matched pairs allowing them to serve as both an experimental and control animal at different stages

of the study. In this case, the dogs were trained to perform distinct tasks on specific devices (e.g., press a key on a toy piano) and were also exposed to additional devices to which they were not trained (to be used in the control scenario). Weeks after this initial training dogs were tested with the same devices in a completely new context. When acting as an experimental dog, access to a reward was granted immediately upon completion of the trained operant tasks via a swinging door that would pop open only after successful completion of the task. When acting as a control dog, access to the reward was independent of the dog's actions and was instead granted after a delay equal to their match partner's latency to complete their task. In this regard, only dogs in the experimental situation had the opportunity to learn that their actions could control the door. Thus any differences in the dogs' behavior between the two situations could be attributed to experimental dogs having the opportunity to learn to control access to the reward. McGowan et al. (2014) noted distinct differences in the behavior of the dogs when they were acting as experimental animals versus when they were acting as controls. Experimental dogs who had the opportunity to learn that their actions were controlling the door (and access to the reward) showed signs of excitement including increased tail wagging and activity, whereas control dogs showed signs of frustration such as chewing of the operant device (never seen with dogs in the experimental condition) in response to the unpredictability of the situation. In this regard it seems that problem-solving opportunities are intrinsically rewarding and that an understanding of personal achievement generates a state of positive affect in both human and nonhuman species alike.

### What's in a Name?

Anecdotally, the phenomenon derives its name from an old tale of Archimedes suddenly solving a problem on how to use water displacement to measure the volume of an object (Eureka is a word from Ancient Greek meaning "I have found it"), where he was so excited by his discovery that he ran through the streets yelling "Eureka!" It is difficult to determine the validity of this tale, but

it paints a perfect picture for illustrating the notion. While the act of suddenly finding a solution to a problem is referred to as an epiphany or insight, the term Eureka Effect describes the positive "Aha!" feeling immediately following the moment of epiphany or insight when a previously unsolvable conundrum becomes unmistakably clear. In general, theoretical accounts of experiencing an epiphany include four defining characteristics: (1) the realization appears suddenly to the individual; (2) the newfound solution seems obvious to the individual and so he/she processes the solution with relative ease; (3) the moment of understanding elicits a positive affective state within the individual; and (4) the individual experiencing the epiphany is convinced that the solution that has suddenly come to him/her is true and thus the solution transforms his/her perspective of the problem (Topolinski and Reber 2010). Typically, immediately prior to the Eureka moment the problem solver is stumped and even though he or she may have explored all the possibilities that have come to mind, he or she is still unable to come up with a solution to the problem at hand. After experiencing some level of frustration the problem solver is able to take a break from his/her mental fixation, stepping back to re-evaluate the problem, and "Voila!" the answer appears suddenly (epiphany). In this instant, this transition from not understanding to spontaneous clarity is accompanied by the Eureka moment, a manifestation of joy or extreme satisfaction.

### Mapping the Moment

Recent studies utilizing brain imaging technologies to investigate neural activation around problem-solving events, where a sudden insight or epiphany are involved in the subject coming to a solution, highlight the emotional connection to such achievements (e.g., Shen et al. 2013). In general, problem-solving activities employ a vast cortical network within the brain. However, insightful solutions elicit distinct neural and cognitive processes that enable problem solvers to suddenly make connections that previously were not apparent (Jung-Beeman et al. 2004). Though a

variety of specific areas of the brain have been implemented in studies of the Eureka moment, heightened activity in the amygdala, which is generally associated with emotion, accentuates the emotional connection to the experience. As noted above (point 3 of the theoretical framework), theory behind insight includes the experience of positive affect as a key component of the occurrence. This positive emotional experience is considered by many as definitive, or at least a clear characteristic, of insightful problem-solving and today serves as the best behavioral indicator to tease out problem-solving that involves sudden insight or an epiphany from other forms of problem-solving (Shen et al. 2015).

### **Why Is Problem-Solving So Emotional?**

From an evolutionary perspective, it makes sense that problem-solving should be emotionally rewarding as the positive emotional response (intense feelings around achievement) should help to solidify memories of the process and/or solution. In this sense, problem-solving achievements should evoke an immediate positive affective state in animals as a means to motivate them to explore, solve problems, and gain insights about their environments, even if the true benefit of these behaviors is in the long term (just as play serves as training for the unexpected). Studies of insight in humans demonstrate that better recall of information results when the solving of problems involves an “Aha!” moment where the solution suddenly comes to the subject by their own accord. This is evidenced through numerous studies examining insightful problem-solving where subjects were presented with a wide range of problems including everything from word problems involving sentence comprehension (e.g., Auble et al. 1979) to video clips of magic tricks (e.g., Danek et al. 2013) and those subjects who reported a positive affective feeling of achievement when they solved the problem through insight had better recall of the information than those subjects who were provided some clues toward the solution and solved the problem through reason or trial and error. Thus, it seems

that the positive feeling associated with the mind’s process of moving concepts from incomprehensible to comprehensible facilitates better recall. In fact, there is ample evidence to suggest that recall is greater for solutions that are generated by an individual versus solutions that are presented to them. In terms of the Eureka Effect in dogs described by McGowan et al. (2014), dogs who were acting as experimental animals, and had the opportunity to realize the connection between their actions and a reward, seemed to better remember the task at hand and be more eager to re-enter the test arena than when acting as control animals. Hence, there may be a memory advantage when individuals are able to produce an answer themselves. This concept is further supported by the fact that dopamine release within the brain has been implemented in the process by which learnings are permanently stored (Bethus et al. 2010; Chowdhury et al. 2012). Thus, it makes sense that animals should react emotionally to their own achievements during problem-solving tasks as, to some degree, heightened states of positive emotion can facilitate learning and memory. Just like for humans other animals can experience cognitive bias, where one’s underlying emotional state can influence one’s cognitive processing of even ambiguous stimuli (Mendl et al. 2009). These ideas come to life on a daily basis when humans are interacting with and training animals. In general animals are much more responsive to positive training that is done in a very playful and rewarding way than they are to negative training techniques. Positive affective feelings around problem-solving may help animals to better identify behaviors that are biologically useful, encourage animals to carry out these behaviors to their benefit in the long term, and help to cement memories around the insights learned through problem-solving.

### **Eureka! In a Nutshell**

There is more to problem-solving than facts, skills, and meeting basic needs; problem-solving has an emotional side and the realization of one’s own achievements elicits positive affective states.

The surge of positive emotions occurring specifically during the moment of understanding, the “Aha!” moment, is a powerful motivator. Given the association between realization of achievement and positive emotions, it may be that opportunities to solve problems, make decisions, and exercise cognitive skills are key to emotional well-being in humans and animals alike.

## Event-Related Potentials (ERPs)

David Luque

UNSW Sydney, Sydney, NSW, Australia

### Definition

Event-related potentials, or ERPs, are the resulting of average the *EEG* signal (see ► “*EEG*,” this volume) locked to a specific event. Therefore, the main function of ERPs is to *study* the brain activity that is elicited because of that event, while it is discarded, the brain activity elicited for everything else. The event under analysis typically is the perception of a stimulus (e.g., an image or sound) (e.g., Thorpe et al. 1996), or the emission of an overt response (e.g., Gehring et al. 1993), although the *EEG* signal can be locked to covert (internal) responses as, for instance, inner speech (Ford and Mathalon 2004).

### Advantages and Disadvantages of the ERPs Technique

Because ERPs are generated from the *EEG* signal, the use of ERPs has the same advantages and disadvantages described for the *EEG* test (see ► “*EEG*,” this volume). In brief, *EEG* is good for studying cortical brain activity with great temporal resolution and is noninvasive and inexpensive. On the other hand, the most important disadvantages of using *EEG* are its poor spatial resolution and that it is not appropriate for studying subcortical brain areas.

We might add another drawback for the ERPs technique. ERPs work under the assumption that the *EEG* signal locked to an event contains both a “true” signal from the brain and some degree of noise. The noise is not elicited because of the event and therefore should take different values each time that the event takes place. Therefore, given a sufficient number of repetitions of the event or *trials*, the average data from all these trials should reflect only *event-related* true signal,

since recordings of noise should cancel each other. The number of event repetitions that you need in order to wipe out all the noise depends on the signal/noise ratio. In most of the cases, the number of event repetitions needed for proper ERPs analysis is relatively high, although it depends on the *components* under study (see below). Consequently, ERPs experiments are usually very long and need many trials. This makes the ERPs technique hard to use for the study of some topics. That is the case, for example, if you are interested in the brain activity associated with the first learning episode of some specific content (you can only learn something for the first time once, although see Luque et al. 2012).

An important advantage of using ERPs is that you can use it for studying *covert* events. That is, you do not need overt responses to register your dependent variable. This feature, plus the great temporal resolution of *EEG*, makes ERPs a great tool for studying the first stages of perceptual/attentional processing (Luck et al. 2000).

### Components

ERPs signal, after the averaging process described before, takes the form of a sequence of positive and negative deflections in voltage. Importantly, this sequence is usually the same for events of the same type (visual events, overt responses, etc.). These deflections are usually called peaks, waves, or *components*. ERPs components were named depending on whether the peak is positive or negative and reflecting the approximate latency of the peak (from the onset of the event). For instance, the N200 component stands for a negative wave (hence the *N*) with its maximal amplitude (peak) at 200 ms after the onset of the event. The latency of each component is only approximate, what makes components’ names sometimes confusing (it is not rare to find a P300 component peaking at 500 ms). To make things more complicated, sometimes the ordinal position of the component in the sequence of peaks is used to name the component, instead of the latency in milliseconds (e.g., P3 would be the third positive peak).

Numerous ERPs studies have investigated the psychological meaning of these components, with variable success. In general, there is agreement that early components (peaking sooner than 200 ms) are easier to relate with underlying psychological processes. For instance, the P1 and N1 components reflect rapid deployment of attention and the first stages of perceptual processing (Hillyard and Anllo-Vento 1998).

The more important ERPs components in cognitive neuroscience are (among others) the aforementioned P1 and N1, the N2 and the mismatch negativity (which might reflect the detection of a perceptual deviant), the P3 (which has been related with working memory), and the N400 (elicited by semantically incongruent stimuli) (for more information, see Luck and Kappenman 2011).

Evoked potentials (EPs) or evoked responses are electrical potentials recorded from a human (or an animal) of the nervous system following presentation of a specific variety of stimuli (visual, auditory, somatosensory), as distinct from spontaneous potentials as detected by electroencephalography (EEG), magnetoencephalography (MEG), electromyography (EMG), or other electrophysiologic recording methods.

Stimuli are characterized by intensity (strength of stimulus), duration (length of stimulus), rate (number of times a stimulus is administered), and repetitions/sweeps (number of stimuli presented to). Evoked potentials are characterized by amplitude, polarity, inter-peak, latency, and morphology (see Fig. 1).

In this session, we focused on the EPs which were recorded by EEG. The EPs are too weak to be seen directly in EEG signals, which are always submerged in noises and ongoing activity of the brain (Misulis and Fakhoury 2001). We employ multiple responses averaged to extract the signal from noise and randomly generated brain activities. In other words, we extract responses to time-locked to stimulus from ongoing background activity (noise and random activities of the brain).

There are mainly three kinds of evoked potentials: steady-state evoked potentials, sensory evoked potentials, and motor evoked potentials.

**Evoked Response Potentials, Fig. 1** EPs

## Steady-State Evoked Potentials

Steady-state evoked potential (SSEP) can be steady-state visual evoked potential or steady-state somatosensory evoke potential, which could be evoked by flicking lights or vibratory stimulation with a certain frequency. The amplitude and phase of the frequency components of SSEP are approximately constant over time. The SSEP-based brain-computer interface (BCI) was presented based on this phenomenon. Steady-state visual evoked potential (SSVEP)-based BCI was firstly presented by Vidal in 1973 (Vidal 1973), which was improved significantly in information transfer rate (Chen et al. 2015) recently. The SSVEP-based BCI could be further improved by combining with other brain patterns. Wang et al. presented a new SSVEP and P300 hybrid BCI system to enlarge the user group. In this system, SSVEP and P300 stimuli would not affect each other (Wang et al. 2015). Steady-state somatosensory evoked potential (SSSEP)-based BCI was implemented for the patients who have weak vision or who cannot control their eye movements. Compared to the SSVEP-based BCI, this BCI system provides lower fatigue and is less annoying. However, the classification accuracy and information transfer rate of SSSEP-based BCI are considerably lower compared to the SSVEP-based BCI.

## Sensory Evoked Potentials

Sensory evoked potentials are usually evoked by visual, audio, and tactile stimuli, which are widely used in clinical diagnostic medicine and intraoperative neurophysiology monitoring. Since sensory evoked potentials can be reliably and stably induced and recognized with classification machine learning methods, they are widely used in brain-computer interface to help disabled patients.

### Visual Evoked Potentials

The first work that applied visual evoked potential (VEP) to BCI system was presented by Farwell and Donchin who used a stimuli matrix of letters or graphical symbols to evoke brain potentials for a speller system (Farwell and Donchin 1988). Recently, VEP-based BCI system has been considerably improved by color stimulus, moving stimulus, face stimulus, and other carefully designed smart stimulus. In 2016, a speller system based on VEP with the relatively high information transfer rate was presented by Townsend and Platsko (2016).

### Auditory Evoked Potentials

Auditory evoked potentials (AEPs) are generated in the cochlea and goes through the cochlear nerve, through the cochlear nucleus, superior olivary complex, and lateral lemniscus, to the

inferior colliculus in the midbrain, onto the medial geniculate body, and finally to the cortex. The patients who have weak vision or who cannot control their eye movements but keep audition could not use visual-based BCI system; however, the audio-based BCI system using AEP could be adopted by them. Hill et al. (2004) presented one of the earliest AEP-based BCI system (Hill et al. 2004). Recently, many studies have been performed to increase the targets and information transfer rate and to develop user-friendly AEP-based BCI systems.

### Somatosensory Evoked Potentials

Somatosensory evoked potential (SEP) is usually evoked by tactile and vibratory stimulus. Brouwer and Van Erp (2010) presented the SEP-based BCI which have some advantage over the visual or auditory systems (Brouwer and Van Erp 2010). This kind of BCI system was applied to the ALS patients with visual/auditory impairment and the stroke patients for recovery of somatosensory function. Recently, it was used for consciousness detection in disorders of consciousness (DOC) patients.

For example, auditory brain stem *evoked* response or *potential* (ABER or ABEP), as very small EP in response to a complex auditory stimulus which contains a range of frequencies. Somatosensory *evoked* response or *potential* (SSER or SSEP), occurs when the nervous system is stimulated by electrical pulses and vibrations.

### Motor Evoked Potentials

Motor evoked potentials (MEPs) could be induced by transcranial magnetic stimulation (TMS), which has been widely used in experiments in cognitive neuroscience. They offer a quantitative way to test the role of various types of intervention on the motor system (pharmacological, behavioral, lesion, etc.) because of the correlation between MEP amplitude and motor excitability. MEPs have not been used in brain-computer interface directly; however, it

was used to assess the treatment function of brain-computer interface.

In summary, evoked potentials are widely used for understanding the relationships between physical stimuli, brain activity, and human cognition. Brain-computer interface is used to build a new bridge between human brain and computer through recognizing the brain activities related to specific stimuli (Jin et al. 2015). Evoked potentials could be evoked by visual, audio, electrical, and tactile stimuli, which are widely used in the BCI systems by designing the stimuli characteristics and sequences according to a special code (Jin et al. 2013). The study of EPs will bring new pathways to improve the BCI systems.

## Evolution of Animal Color Vision

Gerald H. Jacobs  
Department of Psychological and Brain Sciences,  
University of California, Santa Barbara,  
CA, USA

### Introduction

How and why do we see color? Isaac Newton's early studies of light provided a fundamental insight into the "how" question. His observations implied that color is not an inherent property of light or objects, but rather represents a perceptual experience resulting from the effects of light on an active visual system. In his words, "the Rays, to speak properly, are not Coloured. In them there is nothing else than a certain power and disposition to stir up a sensation of this or that Colour" (Newton 1730). Much of the scientific study of color since Newton's time consists of behavioral and biological experiments designed to reveal the nature of the linkages between the characteristics of light reaching the eye and the biological changes and visual experiences that ensue. Significant progress has also been made toward understanding the manner in which color vision may have evolved, thus beginning to illuminate the

"why" question. That process has been facilitated by recent discoveries about visual system biology, and by an expansion of knowledge about the nature and distribution of color vision across a broad range of animal species (Cronin et al. 2014; Kelber and Jacobs 2016).

### Definition of Color Vision

Color is an intimate feature of human experience so it is natural to talk about it using the richly descriptive language of everyday life. The scientific study of color vision, however, requires precise definitions. Fundamentally, light reaching the eye of a viewer from various locations in visual space can vary in its distribution of spectral energies (wavelength variation) and in its total photon flux (intensity). The presence of a capacity to see color – color vision – is formally defined as the ability of a viewer to discriminate variations in wavelength content irrespective of variations in intensity (Wyszecki and Stiles 1982). From a practical point of view this means, for example, that objects differing only in the wavelengths they reflect to the eye must remain fully discriminable irrespective of their relative intensities. Note this definition carries with it an implication about the underlying biology: visual systems capable of supporting color vision must contain an organization that allows some disambiguation of the effects of variations in the intensity and wavelength of light. Beyond this simple criterion for establishing the presence of color vision, many more derived features of color vision can and have been extensively studied.

### Dimensionality of Color Vision and Its Biology

The observations that Newton made on color mixing – the appearances produced by the superimposition of lights having different spectral contents – yielded another fundamental discovery. He found that additive mixtures of various spectral lights (called primaries) produced colors that often differed dramatically in appearance from

that of the primaries themselves. He further showed that results obtained from a variety of combinations of such lights could be economically summarized by plotting them on a circular surface where the primaries are located around the circumference of the circle and the perceptual results of the mixtures then positioned within; the latter falling along straight lines that interconnect the various mixture components. A critical point of this demonstration is that the same perceived color can be produced through the mixture of different primary lights. That fact implies that color vision must have a limited dimensional quality. A century later, Herman von Helmholtz and others expanded color-mixing experiments and found that various mixtures of only three appropriately-chosen primaries are sufficient to match in appearance all other spectral lights so normal human color vision must be three dimensional, i.e., it is *trichromatic*.

The simplest explanation for the trichromacy of normal humans was that there must be a visual system organization that supports a three-way sorting of light-elicited signals. Although there was much theorizing about the nature of such a mechanism, it was not until about 1960 that it became technically possible to show that there are three separate classes of photopigments located in the cone receptors of the human retina. The absorption properties of these three photopigments are sketched in Fig. 1. In such plots, the height of the curve represents the relative probability that light will be absorbed as a function of the wavelength of the stimulating light.

Those absorption events produce an electrical signal in the photoreceptor that is proportional in size to the total amount of absorbed light, independent of the wavelengths of that light. The result is that stimulating the eye with light generates a neural response that is distributed across the three types of cone in accord with the spectral distribution of the incoming light. The outputs from these three are then compared and contrasted in the neural networks of the visual system so as to yield the complete palate of visual percepts, including those features that we describe as colored.

Progress toward understanding the biology of color vision also emerged from another early discovery: within human populations there are some individuals whose color vision differs dramatically from that of most others. Although commonly referred to as being “color blind,” such individuals are better described as having defective color vision. Prominent among them are those who in the basic color matching task are able to match all other spectral stimuli using only two primary lights. Accordingly, their color vision is two-dimensional rather than three-dimensional and they are therefore considered to be *dichromats*. When it became possible to examine their cone photopigments directly, it was discovered that they possess two rather than three types of cone pigment, thus affirming the idea that the dimensionality of human color vision seems tightly linked to the number of cone pigment types. Dichromacy varies in nature among color defectives depending on which of the three types of cone pigment (S, M, or L) is missing. In

# Evolution of Animal Color Vision,

**Fig. 1** Absorption curves for the three cone photopigments found in the human retina. S, M, and L are shorthand designations used to indicate short-wavelength, middle-wavelength, and long-wavelength sensitive photopigments

addition, there are still other color defectives that require three primaries to complete the color matching task, but to do so they select aberrant proportions of the three. Such people are trichromatic, but since they differ significantly from the normal, they are described as being *anomalous trichromats*. Measurements of their cone pigments show that they indeed have three types, but that the spectral positioning of their pigments along the wavelength axis is different from those with normal color vision. Finally – and very rarely – there are individuals who lack color vision completely; they are truly color blind. In a color matching task they can match the appearance of any spectral light with the light from only a single primary and so are classified as being *monochromatic*. The underlying biology of monochromatic color vision includes some complicated individual variations, but in most cases there is only a single active photopigment.

Another long-established fact is that color-defective vision is inherited as a sex-linked trait such that those affected are predominantly male. The total incidence of defective color vision in the population is significant – somewhere around 8% of all males have a color vision defect. The condition is much rarer among females and that difference provided an early key to uncovering a basic feature of color vision biology.

## The Ubiquitous Opsins

Photopigments play a unique role in supporting color vision and thus an understanding of the evolution of color vision requires a little closer look at those remarkable devices.

All animal photopigment molecules consist of two linked components. One is a chromophore, an aldehyde of Vitamin A; the other a protein, opsin. Absorption of the energy from incoming light causes a structural alteration in the chromophore initiating a series of steps that result in an electrical signal from the photoreceptor. It had long been hypothesized that small variations in the structure of the photopigment molecule are responsible for the spectral positioning of their absorption functions, but verification awaited the

development of molecular biological techniques. In 1986, the genes that specify the three human cone opsins were first isolated and sequenced (Nathans et al. 1986). The results showed the structures of the cone photopigment genes are all greatly similar with only small changes in the primary structure of these genes being linked to differences in the absorption spectra of the three cone pigments. For example, only three amino acid substitutions in the cone opsins – out of a total of 365 amino acids – are sufficient to shift the spectral absorption curves across total range encompassed by the middle (M) and long (L) pigments of Fig. 1 (Neitz et al. 1991). This intimate coupling between gene alterations and the spectral properties of the photopigments means that mutational events must have played a critical role in shaping the evolution of color vision.

The opsin gene complements of hundreds of different animal species have now been documented and thus the links between the structure of these genes and photopigment absorption spectra are well established. A consequence is that genetic studies by themselves can yield an indication of the number of photopigment types an animal has and they can provide inferences about their spectral absorption properties. This in turn allows predictions about the nature of vision – including color vision – in animals which have not been otherwise studied. Such results also provide tools for generating hypotheses about the evolution of color vision.

## Opsin Histories

Opsins belong to a large family of proteins (G-protein coupled receptors, GPCRs) that collectively serve as cell-surface receptors whose functions are to detect external inputs and convert these into cellular signals. Comparisons of gene sequences have fostered significant advances in understanding the evolutionary history of opsins. It appears that the ancestral opsin evolved from GPCR precursors about 700 million years ago (Mya) (Feuda et al. 2012). Subsequent gene and whole genome duplications led to the emergence

of several opsin-gene families. Vertebrate and invertebrate visual opsins arose from two of these families (Lamb 2013).

The opsin gene that gave rise to the vertebrate visual opsins duplicated at a time close to the first appearance of vertebrates (~525 Mya). Shortly thereafter, four cone-opsin gene groups emerged. Representatives from these four (identified by the acronyms SWS1, SWS2, Rh2 and LWS) encompass all contemporary vertebrate cone opsins. A fifth group, Rh1, emerged somewhat later from a gene duplication in the SWS1 gene family. Rh1 specifies the photopigment opsins found in the other type of vertebrate photoreceptor, rods. Rods do not normally contribute to color vision. The spectral positioning of the photopigments associated with these opsins depends on the details of their amino acid sequences and on the identity of the chromophore to which these are bound. Photopigments are designated according to the spectral location of their peak sensitivity ( $\lambda_{\text{max}}$ ). For example, when conjoined to retinal-1, a common chromophore, the  $\lambda_{\text{max}}$  ranges covered by the vertebrate photopigments drawn from the cone-opsin groups are: SWS1 (355–440 nm), SWS2 (440–470 nm), Rh2 (480–530 nm), and LWS (500–565 nm).

Broad-scale comparisons of opsin gene sequences allow the construction of opsin-gene phylogenetic trees. One such tree for vertebrate opsins is shown in Fig. 2 where a small number of contemporary vertebrate species drawn from among all those that have been studied are shown to the right. The figure reinforces the point that all vertebrate cone photopigment opsins are representatives from four opsin-gene families. Another fact that emerges from analyses like this, as well as from direct measurements of photopigments, is that not all vertebrates derive opsins from each of the four cone opsin-gene families. Note, for example, that although chicken and zebrafish have opsin genes from all four families, frogs lack representation from the Rh2 gene family and the mouse has opsins from only two of the four (SWS1 and LWS). If all species derived only a single cone pigment from each of the gene families, that arrangement

would predict that chicken and zebrafish have four different cone photopigments, whereas frogs have three, and the mouse only two. Although that inference can be the correct – in fact is for all of those named species – other animals may derive more than a single opsin gene (and a corresponding cone photopigment) from a single gene family. That is what has happened in humans who, thanks to an ancestral gene duplication event, have two separate opsin genes from the LWS family yielding the M and L pigments of Fig. 1. The converse has also happened such that a species may have an opsin gene that fails to express a functional photopigment. That occurred for example in the common hamster, a species whose genome contains opsin genes from both SWS1 and LWS families, but due to the presence of fatal mutations in the SWS1 opsin gene expresses only a single photopigment from the LWS family.

Principally because of the great disparity in their relative numbers, the evolution of invertebrate opsins is less well established than that for the vertebrates. Among the invertebrates, the opsins of arthropods have been the most thoroughly studied (Cronin and Porter 2014). In that group, the visual opsins also fall into four families that specify visual photopigments whose  $\lambda_{\text{max}}$  values occupy different spectral ranges. Many of these invertebrate species have highly diverse photopigment complements, some examples of which are given below.

The phylogenies derived for the opsin genes of different groups of animals reveal rich histories of gene addition and gene loss. These changes have been brought about through the classical mechanisms of gene mutation and gene duplication. These processes allowed various lineages to end up with greater or fewer than the number of genes that might be predicted from the presence of four gene families alone. Additionally, mutational changes in gene structure have served as a primary means to alter opsin spectral tuning and thus change the photopigment absorption properties. All of these events working in concert have fostered a rich range of possibilities on which natural selection operates to shape the complement of photopigments of a species.

# Evolution of Animal Color Vision,

**Fig. 2** Phylogeny of the five vertebrate opsin-gene families. The Rh2 genes specify opsins used for rod photopigments; the other four are for the cone opsin genes. See text for further details (Figure reprinted by permission from Kelber and Jacobs (2016))

## Multiple Functional Roles for Photopigment Signals

To appreciate how the number of photopigment types an animal possesses links to color vision requires understanding the varied roles that photopigment signals play in supporting vision. As noted, photopigments signal the total amount of light absorbed, irrespective of its wavelength. A single photopigment is thus blind to wavelength variation independent of intensity variation – as is required for color vision – and, consequently, an animal possessing only a single photopigment is by definition normally absent of all color vision. Among contemporary species numerous such animals exist; for example, some sharks, whales, mollusks, and deep sea fishes have only a single

photopigment and thus are without a capacity for ordinary color vision. Opsin phylogenies, such as that shown in Fig. 2, imply that ancestral animals acquired multiple types of photopigment at a time early in evolution. A consequence is that contemporary species without any color vision must have lost the potential for that capacity sometime during the evolution of their particular lineages.

The presence of two or more photopigments is usually a prerequisite for having a color vision capacity. But although necessary, the presence of two photopigments is not by itself sufficient to assure color vision. In order to generate signals that can be used to support color vision, the outputs from the two different types of photopigment must be compared in the nervous system. These comparisons occur through the actions of

chromatic-opponent neurons in the visual system that effectively subtract the two photopigment signals one from another (Jacobs 2014). The operation of these cells accomplishes a disentangling of wavelength- and intensity-related changes, thus satisfying the criterion for supporting color vision. Such comparisons made between the signals from two types of photopigment can support a single dimension of color vision (dichromacy). If the two signals are simply added together in the nervous system, these signals may support other visual behaviors but they cannot provide for a color-vision capacity.

Adding photopigments to the eye beyond the minimal two sets the stage for the presence of additional interactive comparisons between different pigment types and those changes serve to increase the dimensionality of color vision. In humans, for example, the presence of three types of cone photopigments allows an additional type of cone photopigment comparison and adds a dimension of color vision, making normal human color vision trichromatic. Adding still further cone pigments beyond three, and increasing the number of appropriate nervous system comparisons, can further increase dimensionality so animals could potentially become tetrachromatic, pentachromatic, etc.

The important point is that although knowing the number of photopigment types an animal possesses can provide predictions about the limits of color vision, that information is not, by itself, a necessarily reliable indicator of the nature of its color vision. To fully understand the nature of an animal's color vision requires results from appropriate behavioral tests.

## Evolution, Photopigments, and Color Vision

There is a large literature covering various aspects of visual photopigments, photopigment evolution, and animal color vision (Briscoe and Chittka 2001; Kelber et al. 2003; Jacobs 2012; Kelber and Jacobs 2016). Although there are still major gaps in our understanding of these topics individually, as well as to how each may interrelate to the

others, several organizational themes can be discerned.

1. *Photopigment evolution and color vision established.* For a number of species, the dimensionalities of their color vision and its evolution have been reasonably well established. Mammals, considered separately below, fall into this group. Among other vertebrates, the opsin gene phylogeny of Fig. 2 shows that a representative bird (chicken), fish (zebrafish), and reptile (green anole) all inherited visual opsin genes from each of the four cone opsin families. That is also the case for many other representatives of each of these three groups of animals. An arrangement like this provides such animals with a total of four cone photopigments. Although there are significant variations in the spectral positioning of these pigments across species, as well as in other features of their visual systems, this arrangement can support tetrachromatic color vision. Actual color vision tests on such species have been relatively infrequent, but in the several instances where these tests have been performed tetrachromacy was in fact established. Well-known examples of tetrachromats in these groups include chickens, pigeons, parrots, goldfish, and turtles.

A number of insects have opsins from three gene families providing the potential for eyes that contain three photopigments and support trichromatic color vision. One such case where trichromacy has long been established is that of the honeybee (Hempel de Ibarra et al. 2014). The three photopigments underlying honeybee trichromacy are all significantly shifted toward the shorter wavelengths, allowing honeybee color vision to extend well down into the ultraviolet wavelengths, a portion of the spectrum invisible to the human eye.

2. *Photopigment swapping.* A recent discovery is that the opsin gene arrays of some animals allow for the production of more types of photopigments than are actually expressed in the eye at any given time. The best examples come from studies of cichlids – small, colorful fishes that inhabit the Rift Lakes of East Africa

(Carleton 2014). As a result of earlier gene duplications, cichlids derive a total of seven distinct cone-opsin genes from the four vertebrate-opsin gene families. Yet only three of these genes are expressed in the retina at any given time. These three can vary across species and also may change in individual animals as a function of their stage of development or in response to the details of the local photic environment. Although thus apparently being limited to having trichromatic color vision, the nature of the trichromacy in these fish shows considerable plasticity. Similar opsin gene/photopigment swapping arrangements seem likely to be more common than is currently appreciated.

3. *Photopigments for specific occasions.* The genomes of some invertebrates have been found to contain significant numbers of different visual opsin genes. This allows the eyes of such animals to contain photoreceptors that feature multiple combinations of photopigments. In some cases, there may be 15 or more such receptor arrangements. The roles played by all of these photopigments often remain unknown, but in some cases the signals derived from these receptors have been shown to support a variety of highly specific behaviors. For example, the eyes of the Japanese yellow swallowtail butterfly contain eight different photoreceptor arrangements (Koshitaka et al. 2008). The outputs from four of these photoreceptor types are used to provide general-purpose tetrachromatic color vision. In addition, signals derived from some of the receptors, taken either singly or in various combinations, are used to trigger stereotyped species-specific behaviors. For example, in many butterflies egg laying on a surface is preferentially triggered in the presence of some spectral lights (typically greenish in appearance to humans), but not in other illuminations. These are usually categorized as being “wavelength-specific” behaviors and they constitute a kind of hard-wired color vision that is distinct from the color vision capacities supported by dimensional color vision (Kelber and Osorio 2010). Wavelength-

specific behaviors are common among invertebrates.

4. *Special case of mammals.* Mammals are special, not just because that is our class, but also because there is a plausible scenario for the evolution of mammalian color vision (Jacobs 2009). Mammals first emerged ~200 Mya. Like other vertebrates, the earliest mammals had representation from all four opsin gene families and thus likely had photopigment arrays sufficient to support color vision, potentially a tetrachromacy. The subsequent evolution of mammalian opsin genes is mostly a story of loss. The timing of most losses is traced to the long period during which mammals were principally nocturnal (from ~200 to 150 Mya), a circumstance where the predominant visual environments (dim to dark) would not have been well served by elaborate color vision capacities. The Rh2 gene family disappeared prior to the divergence of three mammalian subclasses (monotremes, marsupials, eutherians) such that the crown mammal probably had three cone opsin genes with a potential for trichromacy. Subsequently, SWS1 representation disappeared in the monotremes, while SWS2 genes were lost in both marsupial and eutherian lines. A consequence of these losses is that, unlike other vertebrates, the opsins of all contemporary mammals are from only two gene families. Another early event of significance for color vision is that opsin genes of the LWS family were translocated from an autosome to the X chromosome in both marsupials and eutherians. That evolutionary step explains why human color defectives are mostly males.

Eutherians make up most (~94%) of contemporary mammals and with the exception of the primates all these species are limited to having two active opsin genes (from SWS1 and LWS gene families, respectively.) That arrangement predicts that if color vision is present at all, it should be a dichromacy. To the extent that good behavioral evaluations exist that seems to be true. At the same time, many contemporary mammals are either nocturnal or crepuscular and thus

probably enjoy only a limited color vision capacity (Jacobs 2010).

Color vision in primates is unique among that of the mammals. Although many primates acquired a third cone pigment and with it trichromatic color vision, others have two cone pigments and dichromatic color vision (Jacobs 2008). Old World primates (humans, apes and monkeys) added a second LWS gene on their X chromosomes from an early (30–35 Mya) gene duplication and it is normal for such animals to have trichromatic color vision. New World monkeys are different, having polymorphic X-chromosome LWS genes. This arrangement allows those females who are heterozygous at the X-chromosome opsin-gene site to gain two middle-to-long wavelength cone pigments and enjoy trichromatic color vision while males having a single X-chromosome are uniformly dichromatic. There are some notable exceptions to these two basic arrangements, including those nocturnal primates that have only a single LWS photopigment and a nonfunctional SWS1 opsin gene and so lack color vision.

### Utility of Color Vision

A complete account of the evolution of color vision requires both documentation of heritable changes in visual systems that support new capacities and details about how such capacities have yielded adaptive advantages and thus have been maintained in the population.

Over the years, there has been much speculation about the roles that color vision might play in supporting behavior. Two general approaches are currently being used to examine the utility of color vision. One is basically computational, employing detailed measurements of individual photic environment as inputs to models of how visual systems process color signals. The outcomes from variations in model parameters, for example, the spectral positioning of the recipient photopigments, can then be evaluated to see how well the model system performs and from the results determine what arrangements seem most advantageous to support particular visual needs. The

second approach is behavioral, involving either the direct observations of animals as they deal with potential color signals in their environments (for example, as an aid in the harvesting of fruit) or the testing of animals in contrived experimental settings to see how well they perform in the presence of carefully supplied color cues. A particularly useful variant of such behavioral techniques involves comparisons of the performances of individuals of the same species that differ in their color vision, e. g., dichromatic and trichromatic conspecifics such as that seen in the New World monkeys. To date these two approaches are only just beginning to reveal information about the utility of color vision, but it seems likely that they will eventually make major contributions to our further understanding of the evolution of color vision (Jacobs 2015).

## Evolutionarily Stable Strategies

François-Xavier Dechaume-Moncharmont  
Evolutionary Ecology Group, Université de  
Bourgogne Franche-Comté, UMR CNRS 6282  
Biogéosciences, Dijon, France

## Definitions

- *Strategy*: set of (behavioral) phenotypes or decision rules having evolved under natural selection.
- *Evolutionarily stable strategy*: strategy that, when resident (i.e., adopted by most members a population), cannot be invaded by an initially rare alternative strategy (also referred to as mutant).
- *Darwinian fitness*: expected reproductive contribution to future generations.
- *Frequency dependence*: dependence of the fitness payoffs of a strategy on the frequency of the other strategies in a population.

## Introduction

The concept of evolutionary stable strategy (ESS) is an essential part of the behavioral ecologist's toolbox. It belongs to the general field of game theory, which is extensively used to describe and analyze the evolution and the maintenance of (behavioral) phenotypes in a population. Such formal analysis is particularly relevant due to the complex interdependence between the members of a population. The adaptive value of a behavior can rarely be assessed on its own merit irrespective of the behaviors of the individuals from the rest of the population. For instance, the

efficiency of a fighting technique could depend upon its scarcity. While left-handedness does not provide intrinsic mechanical or cognitive benefits in noninteractive sports, being a rare left-handed opponent offers a strategical advantage in many sports involving direct interaction between players as in combat sports, tennis, or cricket (Llaurens et al. 2009). This could be explained by a surprise effect, their opponents being more accustomed to practicing against right-handed players. Consequently, left-handed players are overrepresented in these sports compared to their proportion in the general population. Their frequency increases until their opponents have enough opportunities to be accustomed to their playing style. The proportion of left-handed and right-handed players reaches an equilibrium characterized by the fact that no handedness is advantageous compared to the other.

Such cases of frequency dependence are ubiquitous in nature. For instance, in *Perissodus microlepis*, a small cichlid fish from Lake Tanganyika which feeds on scales of other fish, some individuals are specialized in attacking their prey from the left side, while other are specialized on the right side. The proportions of these two strategies oscillate around 50%. The rarer morph temporarily benefits from lower vigilance by their prey which is more often attacked on the other side by the more abundant morph (Hori 1993). Frequency dependence is not restricted to discrete strategies; it is also relevant for continuous strategies such as the level of selectivity during mate choice. Even when the individuals gain direct benefits from pairing with the highest quality partners, the evolution does not necessarily lead to very selective strategies. Being picky would theoretically allow a female to find a high-quality male if she was the only chooser in the population. But if there are other females competing for the same pool of males, the female would be better accepting even a mediocre partner. A greedy female trying to outsmart her unselective competitors by increasing her choosiness exposes herself to the risk of losing the mate race, all the males being progressively removed from the

pool of potential partners by less selective females while she is unsuccessfully searching for her ideal, yet no longer available, male (Dechaume-Moncharmont et al. 2016). The average partner quality that a female can expect when following a given decision rule cannot be calculated as an absolute value. It is strongly dependent upon the frequency of the other strategies in the population through the background distribution of the remaining male's quality. Searching for the optimal sampling strategy of a given individual thus requires to explicitly consider the behaviors of its competitors.

## Nash Equilibrium

The kind of problems described above, with complex interdependent decision-making, belongs to the general field of game theory, which started to attract considerable attention from mathematicians and economists when von Neumann and Morgenstern's published their seminal book *Theory of Games and Economic Behavior* (1944). Among the family of game theory, one is particularly relevant in biology, the noncooperative game in which the players are not assumed a priori to cooperate or to form binding agreements. The cooperation between the players can emerge from such games as a consequence of the interaction but not as a prerequisite. The central assumption is that the players act rationally and try to maximize their payoffs. The difficulty is to find the possible outcomes from the interactions between the players. A decisive result has been formulated by John Nash (1950), which earned him the Nobel Prize in Economics in 1994. He characterized the solution of a noncooperative game as an equilibrium, which is now referred to as "Nash equilibrium." He gave a very concise definition of this concept which can be summarized as: an equilibrium point is reached when the strategy of the players cannot be strictly outperformed by another strategy. In other words, no player would be tempted to switch strategies because he would not increase his payoffs by unilaterally deviating from the equilibrium point.

## Evolutionary Game Theory

A very strong assumption of the classical game theory is that each player acts rationally, which means that they purposely behave in order to maximize a criterion of self-interest. Yet, the existence of rational decision-making has been challenged many times in experimental psychology. The ecologists considered the problem from a completely different perspective than the economists or the psychologists. William Hamilton and Robert Trivers were among the first biologists to acknowledge the relevance of game theoretical framework in evolution, but the field of evolutionary game theory was founded by John Maynard Smith and George Price (1973). They introduced the concept of *evolutionarily stable strategy*, which is closely related to the Nash equilibrium. The key idea behind the concept of ESS is that the individual behaviors directly affect its Darwinian fitness, namely, its probability to survive, reproduce, and contribute to future generations. The best strategies lead to higher reproductive success, and thus, their frequency increases in the population across generations. On the contrary, the least efficient strategies are progressively washed away by the natural selection. This evolutionary perspective is an elegant way to escape the questionable assumption of perfect rationality in classic game theory, which assumes that agents are able of complex calculation to determine the appropriate action. Evolutionary game theory does not require any cognitive skills for the players. It is the natural selection itself which performs the decision-making procedure: strategies are favored provided they performed well in the environments in which they evolved. This hypothesis of *ecological rationality* is a decisive improvement because the process of natural selection is a clearly defined mechanism. The term strategy could even to be understood in a very broad sense as any set of phenotypes affecting the Darwinian fitness of the individual, as long as they are able of replication: they are heritable and can be transmitted to the next generation. Following that definition, plants, fungus, or microorganisms can perfectly adopt an ESS without any rational thinking. For instance, in bacteria, one can describe the probabilities to

cooperate with neighboring cells and contribute or not to the collective defense as strategies which can be analyzed in a game theoretical framework (Frey 2010).

The concept of ESS is grounded on the existence of mutation which randomly appears in the population. In the evolutionary biology jargon, a mutant is any alternative strategy challenging the resident strategy and trying to invade the population. A strategy is said to invade if, when rare, it does better than the prevailing strategy and so spreads in the population and become the new resident strategy. An ESS is characterized by its stability, i.e., its ability to resist the invasion by a mutant. This property can be formulated in mathematical terms (Maynard Smith, 1982). Write  $W(p, q)$  the fitness of a player following the strategy  $p$  in a population of players following the strategy  $q$ . If  $p$  is the ESS, no rare mutant strategy  $q$  can outcompete  $p$  when it is resident in the population:

$$W(p, p) \geq W(q, p), \text{ for all } q. \quad (1)$$

This first condition corresponds to the Nash equilibrium. It is, however, possible that the rare mutant strategy  $q$  does as well as the resident strategy:  $W(p, p) = W(q, p)$ . While it is not strictly favored by natural selection, the frequency of the mutant may increase by the neutral process of genetic drift. In other words, the average resident strategy in the population is likely to change. In such case, the Nash equilibrium condition verifying that the strategy  $p$  cannot be outperformed (Eq. 1) is not sufficient. To ensure its evolutionary stability, the ESS should also be able to invade other strategies:

$$\begin{aligned} &\text{if } W(p, p) = W(q, p), \\ &W(p, q) > W(q, q), \text{ for all } q \neq p. \end{aligned} \quad (2)$$

The only best response to an ESS is the ESS itself. Note also that the concept of ESS is more restrictive than the Nash equilibrium: every ESS is a Nash equilibrium, but all Nash equilibrium is not necessarily an ESS.

# Evolutionary Stable Strategy and Population Optimality

The concept of ESS has an important heuristic value in biology because it is a powerful argument against group selection as a major mechanism for the evolution of cooperation: most collectively optimal strategies are very fragile and highly unstable when confronted to selfish mutant strategies. To illustrate this point, one can consider the classical example of the producer-scrouter game (Giraldeau and Caraco 2000). In many species, the foraging strategy of the individuals can be categorized in two contrasted

behaviors: the producers actively search for food on their own, while the scroungers try to steal a portion of the food discovered by the producers. Consider a population with proportion  $p$  of scroungers, and  $1 - p$  of producers. The producers are bearing all the costs of active food searching. A scrounger takes advantage of the active food searching of the producers and thus negatively affects its foraging efficiency. The total amount of food per individual, which can be used as a proxy of the fitness payoffs, decreases as the proportion of scroungers increases (Fig. 1). The optimal situation at the group level (group optimum) that would

**Evolutionarily Stable Strategies, Fig. 1** The fitness payoffs of the producers and scroungers are frequency-dependent: they both decrease with  $p$  the proportion of scroungers in the population. The plot should be read vertically: a given state of the population corresponds to a given proportion of scroungers, which allows comparison on both fitness payoffs. For any proportion of scroungers  $q_1 < p^*$ , the scroungers have higher fitness payoffs, and their proportion should therefore increase over time. On the contrary, for any proportion  $q_2 > p^*$ , the producers have higher fitness payoffs, and thus,

$p$  decreases. The only evolutionary stable strategy (ESS) is the proportion  $p^*$ . Any mutant trying to deviate from this proportion will be counter-selected, and the population comes back to the stable point (solid circle). The “group optimum” (in that order), which maximizes the individual payoffs, corresponds to a population of pure producers  $p = 0$  (open circle), but it is an unstable optimum: a scrounger mutant would largely benefit from the producers’ efficiency to locate food and will therefore quickly invade the population up to the ESS point

maximize the payoffs for all the individuals is thus a pure population of producers ( $p = 0$ , open circle in Fig. 1), but it is not a stable state. Indeed, an individual which begins to play as a scrounger largely benefits from its rare behavior, and its expected fitness payoffs are much larger than those of the producers. Consequently, it will have a greater probability of contributing to the next generation, and its behavior quickly spreads in the population. The proportion of scroungers increases up to  $p^*$  (solid circle in Fig. 1) which is the ESS: any deviation from this proportion would be counter-selected. A remarkable feature of such a game is that the ESS (Fig. 1; solid circle) leads to much higher payoffs than the population optimal strategy (Fig. 1; open circle). Evolution does not necessarily comply with the general interest. This idea is very similar to the “tragedy of the commons” in economy (Hardin 1968).

## Future Directions

Since the seminal book by John Maynard Smith (1982), the concept of ESS is not only considered as a central concept in evolutionary biology, but it also attracted the attention of economists (Hammerstein and Hagen 2005; Weibull 1997). The field of evolutionary game theory has developed in many directions. The analysis described above essentially focused on the ESS because it is easier to analyze the equilibrium than the dynamical trajectories leading to the equilibrium. Yet, the ESS is essentially a question of stability around the equilibrium point: the population can both resist the invasion by mutants and move back to the ESS after a perturbation. But the definition of ESS does not guarantee that any potential ESS can evolve in the first place, i.e., when it is the rare mutant itself. The background environment might not be favorable enough to ensure its initial spread. This particular question is specifically addressed by the field of *adaptive dynamics* (Diekmann 2004; Waxman and Gavrillets 2005).

Another important concern about the concept of ESS is related to its heuristic value in animal behavior. Evolutionary game theory essentially

aims at proposing normative models about the outcome of complex interactions between agents and the resulting equilibrium strategy, with limited assumption about the underlying decision-making processes. It is a powerful mechanism to describe the evolution of phenotypes across generation, allowing the application of game theory analysis to any living organisms, regardless of their cognitive abilities, as long as they are submitted to the evolutionary processes of replication, mutation, and selection. It is a convenient way to escape the demanding assumption of classical game theory about the players' capacity to understand the rules of the interactions and to think rationally. It is however important to note that the evolutionary time scale is measured in a number of generations. In other words, the convergence toward the ESS is based on the very slow process of selection of the most efficient strategies across generations. This mechanism is not relevant for most behaviors of interest. The animals constantly make short-term adjustments of their behaviors in response to changes in the social context. These adjustments can occur through learning, reinforcement, trials and errors, copying, or cultural transmission. Superficially, these mechanisms appear consistent with the fundamental mechanisms at the very basis of the evolutionary game theory: if a new behavior (mutation) performs well (selection), it could be adopted by other members of the population (replication). But they also assume advance cognitive skills such as memory, ability to compare the frequency-dependent payoffs, learning, and behavioral flexibility. The apparently simple ecological mechanisms invoked in the definition of the ESS had led many behavioral ecologists to disregard the question of the underlying decision-making process. At most, they assumed that the underlying cognitive machinery itself should evolve by natural selection in order to generate behaviors close to the ESS. It is still an open question whether the limited learning skills allow the convergence toward strategies close to the ESS (Fawcett et al. 2013; Hagen et al. 2012). Even if the concept of ESS has an enormous interest as a normative model, it might be of very limited interest as a descriptive model

because it fails to encapsulate the underlying processes of decision-making. Hopefully, these mechanisms are currently the object of a growing interest in behavioral ecology (Fawcett et al. 2014), and this research could, in turn, spawn new development in game theory.

## Synonyms

Spandrels

## Definition

Biological and psychological traits can have an adaptive function (i.e., adaptation) or appear as a (nonadaptive) by-product of another adaptation (i.e., spandrels or by-product).

## Evolutionary Psychology

Evolutionary approaches have become very popular in many areas of the behavioral and social sciences. Evolutionary psychology argues that

most human behaviors can be explained by internal psychological mechanisms and claims that the reason for these mechanisms to have emerged in our evolutionary past is to provide solutions to the adaptive problems our ancestors have faced. In other words, many of these psychological mechanisms exist because they provided a solution to problems related to survival and reproduction in the past. The main purpose of evolutionary psychology as a research program is to identify these psychological mechanisms directing behavior that are the product of evolutionary processes. What we mean by a psychological mechanism are mental capacities like the ability to acquire language, the ability to detect cheating, the tendency to make moral judgments, the tendency to learn about the fear of snakes, the ability to recognize relatives, the tendency to find certain characteristics of the opposite sex attractive, and the ability to identify others' cognitive and emotional states.

According to this view, human behavior is not a direct product of natural selection; instead, psychological mechanisms evolve as a result of natural selection (and other evolutionary processes) and behavior emerges as a result of an interaction between these mechanisms and environmental conditions. The brain is a kind of computer that has developed to collect inputs from the environment. Programs in the brain are adaptations. All of these adaptations may not be adaptive at present, but they were adapted to the environmental conditions in which our ancestors lived (Tooby and Cosmides 2005). In this sense, evolutionary psychology differs from cognitive psychology. While both address the importance of internal mechanisms in influencing behavior, evolutionary psychologists also focus on what ultimately explains these behaviors; that is, whether they contributed to the survival and reproductive success of our ancestors. Cognitive psychologists, on the other hand, are content with providing only proximal explanations of these behaviors.

A second assumption in evolutionary psychology is that the mind is modular. That is, different adaptations have emerged in humans to solve many different adaptive problems they encounter in the environmental conditions they evolved. Therefore, according to this point of view, the

mind should consist of many different modular mechanisms for solving specific problems rather than a single mechanism for solving general problems. In other words, just as there are different organs in the body having different functions, the mind may also consist of different adaptations of this kind.

In evolutionary psychology, there are two different levels of explanation. The first is the ultimate explanation that reveals the evolutionary roots of behavior (explains why and how it evolved) and reveals its underlying foundations. For example, the proposal that the reason language evolved is that it promotes interhuman cooperation is a kind of ultimate explanation. The proximate explanation, on the other hand, deals with elucidating the psychological and neurobiological underpinnings of that behavior. For example, the proposal that the reason we help our sibling is our emotional closeness to him/her is a kind of proximate explanation.

Although evolutionary psychology has been subjected to quite a bit of criticism from both philosophers and biologists to date (e.g., Buller 2005; Richardson 2007; for responses, see Hagen 2015; Confer et al. 2010), it has become quite popular in recent years. One of the reasons for its popularity is the theoretical developments in evolutionary biology, especially in the second half of the twentieth century. These developments include William Hamilton's idea of inclusive fitness and kin selection; George Williams's books that led to the drop of the idea of group selection off the map; Robert Trivers's reciprocal altruism, parental investment, and parent-offspring conflict theories; and game theory and the concept of evolutionarily stable strategy that John Maynard-Smith carried from economics to evolutionary biology. In addition to these advances in biology, evolutionary psychology has also gained tremendous popular support over the past 20 years. In addition to the theoretical developments listed above, Edward Wilson's *Sociobiology* book, which is an excellent synthesis of the evolutionary foundations of social behavior, and Richard Dawkins' book *The Selfish Gene* popularized all these ideas and presented them in a new perspective (Buss 2012).

## Adaptation and By-product

According to the adaptive view of the modern evolutionary approach based on Charles Darwin's theory of natural selection, biological features can have an adaptive function (i.e., adaptation) or appear as a by-product of another adaptation (i.e., spandrel or by-product). Although evolutionary by-products do not directly lead to adaptive advantage, they emerge as a derivative of another adaptation that leads to adaptive advantage. To give an example of by-products in this situation, the umbilical cord can be taken as a typical example of adaptation due to its function of allowing nutrient exchange between the placenta and the embryo. As far as we know, the belly button, which does not directly lead to adaptive advantage, is a by-product of another adaptation (i.e., umbilical cord) because everyone who has an umbilical cord has a belly button. This explains why, although not adaptive, by-products persist in the population for generations.

In addition to adaptations and by-products, there are individual differences that occur entirely by chance, as far as we know, which we will define as a random product. In other words, although the belly button appears in all members of the species, the shape of the belly button varies from person to person, and this can be defined as the accidental variation due to the by-product that does not have any adaptive function.

One of the main difficulties in evolutionary approaches is the process of deciding what is an adaptation and what is a by-product. Especially in the field of evolutionary psychology, this ambiguity is more tangible than in evolutionary biology because one of the preconditions to be able to call something an adaptation is that trait have a genetic basis. However, we have very limited knowledge about the genetic basis of many psychological processes and behaviors, because psychological behaviors are generally not affected by a single gene as they are complex structures, but are formed as a result of the interaction of many genes. This makes it difficult to identify the genetic origins of many psychological processes underlying behavior. Apart from having a genetic basis, adaptations should be seen in all members

of the species, except for those specific to gender. The fact that this feature is seen in all members is an important indicator that distinguishes adaptations from other features, as it is a direct reflection of the evolutionary process and gives species-specific functionality. The third criterion is that adaptations arise in the process of development and therefore do not have to be innate. Another important feature of adaptations is that it solves a problem in the past environment effectively and economically (see Schmitt and Pilcher 2004, for an in-depth discussion of the criteria to be used in identifying psychological adaptations).

## Adaptation or By-product?

In this final section, we will illustrate the adaptation-by-product debate on the basis of several proposed psychological mechanisms. It has been argued, for example, that religious belief is an adaptation that arises due to its promotion of intragroup cooperation through the fear of supernatural punishment (Johnson 2015). In other words, according to the adaptationist view of religion, religion provides a very effective solution to the problem of free-riding due to its reliance on belief in supernatural agents, which has the capacity to punish every moral transgressor by monitoring every human behavior. According to this view, often referred to as *the supernatural punishment hypothesis* (Johnson 2015), interindividual punishment involves a potential risk (e.g., the risk of retaliation), but belief in a supernatural observer who is always watching people and punishing norm violations, solves this evolutionary problem. Because when someone violates traditional moral norms, the idea of supernatural monitoring will encourage people to stay in line. Overall, according to this view, religion emerged as an adaptation as it fostered interpersonal cooperation.

However, an opposing view claims that religion emerged as a by-product of other adaptations (Boyer 2001). According to this view, there are certain evolved adaptive cognitive features and abilities in our mind which emerged as adaptation such as the ability to mentalize. As a by-product of

believing that other people have independent minds, belief in nonphysical supernatural agents has emerged. According to this idea, we can mentalize supernatural beings such as jinn, angels, and devils in our minds, just as we are aware that other human beings have mental states. When Gould and Lewontin (1979) first proposed the idea of evolutionary by-products (i.e., spandrels) in their famous article written in 1979, they claimed that it may not be a secondary feature. Instead, they claimed that a feature that emerges as a by-product could later come to have an adaptive function, often referred to as “exaptation.” According to this idea, even if religious belief has emerged as a by-product, it can be construed as an exaptation since it later gains an adaptive function and encourages cooperation among people.

One of the most popular disputes on adaptation/by-product distinction has taken place in the area of the evolution of language. Noam Chomsky has argued that language and universal language faculty emerged as a kind of by-product (Hauser et al. 2002). According to this view, language emerges as a kind of by-product of the development and complexity of the brain. However, a group led by Steven Pinker and Jack Jackendoff argue that Chomsky’s statement is not very convincing, and language can be an adaptation itself due to its various adaptive benefits (Pinker and Jackendoff 2005). According to this view, language has emerged as an adaptation on its own in terms of its functional solutions in issues such as low-risk punishment (i.e., gossip), interpersonal cooperation, and child-rearing. Therefore, it can be concluded that deciding what is an adaptation and what is a by-product is difficult, especially in evolutionary psychology.

The moral foundations theory (Haidt 2012), which led to a paradigmatic change in the field of moral psychology, also explains morality through evolved adaptations. According to the moral foundations theory, there are five different intuitive foundations (harm, justice, loyalty, authority, holiness), each of which has its own evolutionary function. The care/harm foundation is defined as the behavior shown by other group members to the weaker group member in need of

protection or care. The fairness/cheating, on the other hand, is the moral sensitivity that is required to ensure justice and maintain order within the group. The loyalty/betrayal has been defined as protecting the interests of the group without betrayal. The authority/subversion is defined as another moral sensitivity that is important for mammalian groups living a hierarchical social structures. Finally, the sanctity/degradation describes a moral sensitivity that is thought to have evolved due to a sensitivity to disgust. This alleged evolutionary adaptation, protecting the environment necessary for clean living in natural life and keeping group members away from diseases caused by microbes and bacteria, also affects the moral sensitivity of people. However, since the mechanisms proposed by evolutionary psychologists rarely meet the necessary criteria of identifying a trait as an adaptation, future empirical work, especially in genetics, are warranted to reach a clear conclusion.

## Evolutionary Psychology

Elena Racevska

Department of Social Sciences, Faculty of Humanities and Social Sciences, Oxford Brookes University, Oxford, UK

Evolutionary psychology is a discipline of psychology that examines psychological mechanisms from an evolutionary perspective. Some authors do not consider it to be a distinct branch of psychology, but rather a “theoretical lens that is currently informing all branches of psychology” (Buss 1998). The central aim of evolutionary psychologists is to identify which psychological traits

can be considered adaptations – functional products of natural or sexual selection in human evolution.

## History of Evolutionary Psychology

Evolutionary psychology, albeit relatively new as a scientific discipline, dates back to Charles Darwin. In his book *The Origin of Species* published in 1859, Darwin predicted that “psychology will be based on a new foundation, that of a necessary acquirement of each mental power and capacity by gradation” (Darwin 1859). As an academic discipline, evolutionary psychology developed on the basis of cognitive psychology and evolutionary biology, but its beginnings were also influenced by behavioral ecology, ethology, genetics, anthropology, paleoanthropology, and biology. More specifically, the evolutionary thinking in psychology was prompted by the animal behavior studies of Nikolaas Tinbergen, Konrad Lorenz, and Karl von Frisch in the 1930s and 1940s; William D. Hamilton’s research on inclusive fitness in the 1960s; Robert Trivers’s work on reciprocity and parental investment, and John Maynard Smith’s evolutionary game theory and introduction of the evolutionary stable strategy in the 1970s. Edward O. Wilson combined evolutionary theory with studies of animal behavior and sociality, earning his name as “the father of sociobiology.” Stemming from ethology, sociobiology was first defined as “a systematic study of the biological basis of all social behavior” (Wilson 1975). An additional branch that emerged from ethology is behavioral ecology, the focus of which was on the ecological and evolutionary basis of behavior. George Williams’ 1966 book *Adaptation and Natural Selection: A Critique of Some Current Evolutionary Thought* outlined a gene-centered view of evolution, later popularized by Richard Dawkins’s *The Selfish Gene*, published in 1976.

One of the first publications in which evolutionary concepts were shown to be applicable to humans is “The Evolution of Human Sexuality” by Donald Symons, published in 1979. Herein the author discusses how various aspects of human

sexual anatomy and behavior, such as ovulation, female orgasm, homosexuality, promiscuity and rape, are results of human evolutionary history and can be viewed as adaptive traits (Symons 1979). Despite some criticism, the book is by many considered the most important book on human sociobiology.

*The Adapted Mind: Evolutionary Psychology and the Generation of Culture*, published in 1992 by Jerome H. Barkow, Leda Cosmides, and John Tooby is widely regarded as the foundational text of evolutionary psychology. This is an edited volume of commissioned, empirical research papers on topics such as cooperation, mating and sexual behavior, parental care, perception and language as adaptations, environmental aesthetics, intrapsychic processes, and cultural phenomena (Barkow et al. 1992). According to the authors, the goal of the publication was to introduce the field of evolutionary psychology to a wider scientific audience, as well as to clarify how this field will supply the necessary connection between evolutionary biology and complex social and cultural phenomena. Some of the most prominent evolutionary psychologists, such as Steven Pinker and David Buss, are among the 25 authors who have contributed to the book.

The publication includes an essay by Donald Symons entitled “On the use and misuse of Darwinism in the study of human behavior.” Using the examples of human reproductive strategies and sexual attractiveness, Symons pointed out that Darwin’s theory of evolution by natural selection only explains human behavior as well as it explains its adaptive value. From his point of view, the link between Darwinian theory and behavior is psychology, especially evolutionary psychology. One of the most influential parts of “The Adapted Mind” is the highly-cited essay by Tooby and Cosmides entitled “The psychological foundation of culture.” Herein the authors discuss the social sciences’ lack of progress, which they blame on these disciplines’ insufficient exploration and acceptance of their logical connections to the other sciences. The authors suggested an abandonment of the so-called Standard Social Science Model (SSSM) – a dominant paradigm in the social sciences during the twentieth century,

which they described as “the consensus view of the nature of social and cultural phenomena that has served for a century as the intellectual framework for the organization of psychology and the social sciences and the intellectual justification for their claims of autonomy from the rest of science” (p. 23). Instead, they argued that it should be replaced by a new framework, which they have named the “Integrated Causal Model” (ICM). They believed this would enable progress through acceptance and exploitation of the natural connections that exist among all branches of science.

As outlined in the essay, the SSSM is based on several assumptions, the majority of which are in opposition to the considerations of the ICM. For instance, the SSSM proposes that humans are, apart from the capacity to learn, born as “blank slates” (Hampton 2004). When they are born, infants lack complex adult behaviors, which are only acquired during the course of development, and are products of exposure to the cultural and social elements. Because the individuals are molded by these external sources, they are the creations of the social world. Ideas, values, behaviors, and even the complex emotions are cultural products and can only be explained by the social conditions. The ICM counterargument states that humans are born with numerous emotional, motivational, and cognitive adaptations. While the SSSM sees human brain as a “general purpose” computer, considering all mechanisms and processes of the human mind to be content-free and content-independent, the ICM argues that the brain is a collection of domain-specific modules. Domain specificity entails these modules being evolved to only solve problems in particular domains, which makes them unsuitable for solving problems of other domains.

According to the SSSM, genetic variation does not explain why many human behaviors are shared within groups, but not between groups. As stated by the so-called *psychic unity of human-kind* postulate, formulated by Adolf Bastian, a German ethnologist, all humans, regardless of culture and race, share the same psychological and cognitive make-up. While infants’ behavior does not cross-culturally differ, behavior of adults can differ to a great extent. The inability of

genetics to explain the major differences between thought and behavior of human groups across the world is the only feature of the SSSM that the authors consider to be correct, and which they have thus incorporated into the ICM. They, however, believe that the reason behind this lies in the complex psychological and physiological adaptations that SSSM denies. The ICM acknowledges the role of interactions between the external influences of culture and environment on one side, and the evolved psychological influences on the other side in forming human behavior.

Building from the notion of content-free nature of the human mind, the SSSM views human culture as free to develop in any direction. The ICM, however, argues that the foundations of culture lie on and are constrained by the universal human nature. This illustrates the contrasting views on biology held by the SSSM and the ICM supporters. While SSSM believes biology to be of relatively low importance in understanding human behavior, the ICM accentuates the relevance of understanding the interactions between nature and nurture.

The SSSM-ICM disjunction encountered some criticism, with some authors accusing Tooby and Cosmides of creating a false dichotomy, and arguing that the SSSM was introduced as a term solely for the purpose of pleading in favor of the ICM and evolutionary psychology. However, the success of the SSSM validated its characterization as a paradigm, and it has since been adopted by numerous researchers (Hampton 2004).

## Central Premises of Evolutionary Psychology

### The Massive Modularity Hypothesis

To better understand the discipline of evolutionary psychology, it is necessary to consider the concepts, principles, and hypotheses from which it stems. One of the central premises of evolutionary psychology is that the human mind (or the brain) is an information processing device which produces behavior in response to external and internal inputs. This approach, common in cognitive psychology, stems from the *computational*

*theory of mind*. Evolutionary psychologists propose that brain is composed of modules, which account for all sophisticated human behavior and are units of mental processing designed by natural selection. The so-called *functional architecture* of mind has historically been divided into two different theories: *horizontal* – viewing mental processes as interactions between various faculties that are not domain-specific (such as memory or perception), and *vertical* – claiming that the mental faculties are genetically determined, associated with particular neurological structures, computationally autonomous, and can be distinguished based on their domain specificity. This kind of adaptationist view of physiological mechanisms comprising different modular adaptations that serve different functions is common in evolutionary biology. Evolutionary psychologists believe the human mind has been shaped by natural and sexual selection. For this reason, the many cognitive modules it comprises are specialized for solving particular adaptive challenges that occurred in humanity's evolutionary past. Examples of these modules include language acquisition, incest-avoidance, cheater-detection, mate preferences, foraging, and intelligence.

### Environment of Evolutionary Adaptedness

Another core assumption of evolutionary psychology is that brain is, just like all the other parts of human body, designed and adapted to the conditions of the ancestral environment in which it has evolved. Much of the modern human behavior is considered to be a product of psychological *adaptations* that have evolved to solve problems that were recurrent in the species' *Environment of Evolutionary Adaptedness* (EEA). Evolutionary psychologists develop and examine hypotheses deriving from the idea that conscious as well as unconscious behaviors have evolved to maximize the inclusive fitness of the individual performing them.

Since the human brain has evolved to deal with problems that were recurrent in the EEA, it can have difficulties comprehending and dealing with situations that did not exist in the ancestral environment. This concept is also known as the *Savanna Principle* (Kanazawa 2004). Due to the

insufficient stability of the human environment, the human brain has not experienced significant changes since the Pleistocene (Kanazawa and Perina 2012). According to the Savanna Principle, the brains of modern humans are, in respect to the ability to deal with the challenges that were present in the EEA, similar to those of the species' ancestors. Such issues are referred to as *evolutionary familiar*, and among others, include mate choice and food preference. The adaptive behaviors that provided an advantage in survival and reproduction in the EEA are the ones that humans have retained to this day. However, besides the recurring trials that human ancestors encountered daily, the EEA would occasionally present new and unusual problems. Certain individuals were better able to understand and deal with such non-recurring stimuli that are now commonly referred to as *evolutionary novel*. According to the *Savanna-IQ Interaction Hypothesis* (Kanazawa 2004), those individuals were endowed with higher general intelligence. This hypothesis suggests that intelligence is a domain-specific psychological adaptation that evolved to solve evolutionarily novel problems. The individuals with higher general intelligence should therefore be better able to understand and deal with situations that were not present in the EEA. Since better understanding of a stimulus encompasses an increased likelihood of its preference, this ability also affects values and preferences.

### Adaptiveness of Modern Humans' Behavior

The behavior of nonhuman animals, as well as humans can be interpreted at four levels of analysis, which are jointly called *Tinbergen's Four Questions* (Tinbergen 1963). These questions divide behavioral explanations into two categories – *ultimate* and *proximate*. Ultimate or evolutionary explanations focus on the function of behavior in terms of its adaptive value for survival, and phylogeny, or how a behavior evolved. These types of explanations are based on the comparison of behavior between closely related animal species, or that of different species living

in the same environment, as well as the study of selection on the evolution of behavior. They answer the “why?” questions. Proximate explanations concentrate on behavioral mechanisms and causes of particular behaviors, as well as their ontogeny or development during organism's lifespan. They aim to answer the “how?” questions. Evolutionary psychology primarily focuses on the former, explaining behavior in terms of the processes and the forces of evolution. Function or the adaptive value of a behavior describes the contribution of a particular behavior to animal's reproductive fitness or survival.

Tinbergen argued that behavior is no different from physiological characteristics, in that it has evolved as a means for survival. Just as selective pressures over time alter the physiology, they also alter the behavior. If a behavioral strategy is adopted by an entire population inhabiting a particular environment and cannot be replaced or invaded by any other strategy through the means of natural selection, it is considered an *evolutionarily stable strategy* (ESS) (Taylor and Jonker 1978). ESS rests on two conditions: an individual employing such strategy must do better than an individual employing a different strategy, and should a new strategy evolve, the individual employing the initial strategy must still do better than an individual employing the newly evolved one.

Not all traits can be considered adaptive. Some would be more accurately defined as *exaptations* – “preexisting traits that take on new beneficial effects without being modified by new selection pressures” (Buss 1998, p. 125). This term, introduced in 1982 by Stephen J. Gould and Elisabeth Vrba refers to the characteristics that were originally shaped by natural selection for a particular function (an adaptation), but were later co-opted for another use. They are common in both anatomy and behavior. Conversely, as the environment changes, some of the originally adaptive mechanisms can also become unsuitable. *Evolutionary mismatch*, or *evolutionary trap*, refers to the evolved traits that were once advantageous becoming maladaptive in the current environment (Lloyd et al. 2011). The mismatch hypothesis often attributes this transition to rapid

environmental change. This has been observed in humans, as well as in nonhuman animals. In human evolution, an evolutionary mismatch occurred after the transition from a hunter-gatherer lifestyle to an agricultural one – about 10,000–12,000 years ago. This changed the way humans interacted with the environment, but the evolution of human bodies was too slow to cope with the advancement of the Western cultures. As a result, the adaptations to the previous foraging lifestyle have persisted. Some of the consequences of this mismatch are obesity, metabolic syndrome, osteoporosis, and the increase in allergies and autoimmune diseases. Furthermore, the reward system of dopaminergic pathways of the human brain programs that are programmed for continual pleasure seeking, while adaptive in hunter-gatherer societies is over stimulated and abused in the present environment by activities such as gambling, drug use, and overeating, leading to addictive behaviors.

Another example of an evolutionary mismatch are the responses to *supernormal stimuli* – exaggerated versions of stimuli to which there are existing response tendencies, but which elicit the reaction more strongly than the ones for which it has evolved. The term was coined by Nikolaas Tinbergen. Dr. Deirdre Barret, a psychologist, argued that human behavior is just as influenced by supernormal stimulation as is the behavior of other animals. In her 2007 book *Waistland: A (R) evolutionary View of Our Weight and Fitness Crisis*, the author explained that human instincts are designed for the African savannah in which the species evolved. She further explained how junk food exploits the cravings for salt, sugar, and the fats. She provided another example of a supernormal stimulus in television, which comprises many amplified social cues – like laughter, smiling faces, or attention-grabbing action (Barret 2007). In 2010, Barrett published another book, *Supernormal Stimuli: How Primal Urges Overran Their Evolutionary Purpose* (Barrett 2010). Herein the author applied the concept of supernormal stimuli to the disassociation between human instincts and the current environment to which they have not had the time to adapt to. According to Barrett, this dissociation is the

reason behind the appeal of television, pornography, and video games, as well as being at fault for many of the problems humanity is faced with, such as obesity and warfare.

## Areas of Research in Evolutionary Psychology

In response to evolutionary pressures, humans have developed complex social behaviors and the elaborate brain structure that supports them. The neocortex of humans is larger than that of other primates or mammals of similar size and comprises many areas thought to be involved in higher social cognition – for example, language, regulation of behavior and emotions, empathy, and theory of mind. A lot of research within the field of evolutionary psychology has been done on the various aspects of human social lives and the adaptations that enable their complexity.

### Sociality and Altruistic Behavior

Humans are highly social and many of the adaptive problems the species has faced are linked to social interactions. Social exchange of goods, services, or kindness is considered the very basic fact of human sociality, and although present in only a small number of species, it is present across numerous human cultures (Cosmides and Tooby 2005). Providing benefits to others who will later reciprocate is beneficial to the individual originally providing the benefit. As a result, both individuals are better off. For the social exchange to evolve, the species that engages in it must be able to detect cheaters – i.e., individuals who obtain benefits without reciprocating them. *Cheater-detection mechanism* has evolved to solve the evolutionary problem of detecting cheaters in situations of social exchange. This mechanism looks for cheaters themselves, as opposed to the behavior of cheating, as the behavior itself could be a result of a mistake. Despite the high sociality of the human species, some evidence suggests there is a cognitive limit to the number of stable social relationships an adult can maintain. This number is called *Dunbar's number*. It was proposed by a

British evolutionary psychologist and anthropologist Robin Dunbar (Dunbar 1992). Extrapolating from the results obtained from studying non-human primates and using the average human brain size, he projected that humans can only maintain 150 stable relationships, and that groups of larger sizes will likely require more restrictive rules to maintain their cohesion.

*Altruism* occurs when an instigating individual suffers a fitness loss while the receiving individual experiences a fitness gain. Altruistic behavior will be positively selected for if the benefit to the recipient multiplied by the genetic relatedness of the recipient to the performer is greater than the cost to the performer of a social act. This is known as *Hamilton's rule*, and it stems from research carried out by William D. Hamilton. A failure to satisfy the Hamilton's rule leads to selfish behavior. *Kin altruism* is altruistic behavior, the evolution of which has been driven by *kin selection* – an evolutionary strategy favoring the reproductive success of an individual's genetic relatives, even at a cost to the individual's own survival and reproduction. It is an example of *inclusive fitness*. Inclusive fitness is the number of *offspring equivalents* an individual rears or otherwise supports through its behavior. A direct offspring carries 50% of each of their parents' genes and is considered to be one offspring equivalent. An offspring of a sibling with whom an individual only shares 50% of genes only carries 25% of said individual's genes and is considered 1/2 offspring equivalent. From the gene's perspective, evolutionary success will increase as a function of the number of copies of the gene in the population. This is achieved not only through leaving a maximum number of viable offspring – or increasing personal fitness – but also through increasing the fitness of genetic relatives, as they are likely to carry copies of the same genes. This is called *kin selection theory*. In evolutionary psychology, a degree of genetic relatedness can be used to predict altruism. Relatives who share more genes invest more resources. Furthermore, there is a preferential investment in more certain kin. Mothers' mothers invest the most, followed by mothers' fathers, then fathers' mothers, and finally fathers' fathers. These differences have

been explained by theories of paternal uncertainty (Buss 1999).

When an organism acts in a way that temporarily reduces its own fitness, while increasing that of another, with the expectation that the favor will be returned at a later time, such behavior is considered *reciprocal altruism*. This concept was introduced by Robert Trivers to explain the evolution of *cooperation*. When organisms work together towards a mutual benefit, it is considered cooperation. Any adaptation that has evolved to increase the reproductive success of the acting individual's social partners, at least in part, can be regarded as cooperation. It carries direct fitness benefits (by-products of cooperation) and indirect fitness benefits (resulting from cooperation with genetically similar individuals). *Multi-level selection theory* posits that selection for cooperation happened on multiple levels – from the level of atoms and cell molecules, to the level of individual organisms, community level, and finally the level of the species. Drawing from the classic example of cancer spreading through an organism through the success of individual (cancer) cells that prevail in their efforts to multiply, which ultimately diminishes organism's chance at survival, and hence reproduction, this theory explains that this type of cooperation causes individuals to avoid behaviors that would ensure short-term benefits for themselves, but would be detrimental to the community in the long term.

The most famous example of cooperation comes from the *game theory*, and it is called the *prisoner's dilemma*. It explains why two rational individual might not cooperate, even if such cooperation would seemingly be in the best interest of them both. It was developed by Merrill Flood and Melvin Dresher in 1950, but named by Albert W. Tucker. It describes a situation of two prisoners who have been caught and are individually presented with an opportunity to either betray their partner or cooperate with them. If both choose to cooperate, each will receive a sentence of 1 year in prison, and if both betray their partner, both will receive a doubled sentence of 2 years in prison. However, if one of them betrays their partner, while the other cooperates, the cooperating one will receive a 3-year sentence, while the betrayer

will be freed. As betrayal carries a greater reward than cooperation, all rational “prisoners” should betray each other, but results often show a systemic bias towards cooperation.

While the complexity of the brain structures that guide social behavior implies many benefits, maintaining the size and the high level of sophistication also brings many costs. Development of such a complex system to full capacity takes a long time, which is reflected in a comparatively prolonged developmental period. Providing a stable social environment from responsive and caring adults during individual’s childhood is of high importance for the development of a secure attachment style, which can persist throughout the lifespan.

### Language and Communication

Evolution of human communication is one of the most intriguing areas of research within this discipline. Despite being researched for several centuries, the consensus on the exact origin and age of human language still has not been reached. Due to a lack of direct evidence, a lot of research involves a comparative approach and investigation of communication systems used by other animals, especially nonhuman primates. There are several hypothesis and theories explaining the evolution of language, mainly proposing that language developed from ancestral vocalizations, or that it developed from gestures.

According to a theory put forward by Robin Dunbar, human gossip serves a purpose similar to grooming in other primate species, allowing for the maintenance of relationships and alliances based on reciprocity (“if you scratch my back, I’ll scratch yours”). In his grooming hypothesis, Dunbar proposes that as human groups became increasingly bigger, manual grooming became too time-consuming. An energetically cheaper form evolved in the shape of vocal grooming, which gradually evolved into vocal language (Dunbar 1996). This hypothesis, however, has trouble explaining how meaningless sounds developed into complex syntactical speech.

The *ritual-speech co-evolution theory* argues that language is not a separate adaptation, but an internal aspect of symbolic culture. Verbal

communication is easy to fake, and in many early cultures, trust was established in collective rituals. To understand how language evolved, it is necessary to address the emergence of symbolic culture.

The *gestural theory* suggests language developed from nonverbal, gestural communication, which preceded vocal communication. It is hypothesized that bipedalism played an important role, as it made both hands available for gesturing. The switch to vocal communication was selected for because it freed the hands for other functions.

The evidence for this theory often comes from comparative and biological psychology. For example, nonhuman primates use numerous gestures as means of communication, many of which resemble those used by humans. Gestural communication, especially pointing, is an important part of teaching children to use language. Furthermore, both gestures and spoken language are processed by a common, modality-independent neural system, which links meaning with symbols, and therefore plays a more general role in human communication.

Unlike the vocalizations of many animal species, human words are unreliable signals because they are easy to fake. For a language to fulfill its purpose, listeners need to be able to distinguish lies from honesty. William Tecumseh Fitch, an American evolutionary biologist, proposed the *mother tongue hypothesis*, according to which language initially evolved for communication between mother and the offspring and has later been expanded to include other relatives (Fitch 2004). This explanation is similar to the Darwinian principle of kin selection: genetic interest led individuals to trust the unreliable signals of human words. Simon Baron-Cohen argued that evolution of language was preceded by the evolution of *theory of mind*. Empirical evidence from developmental and cognitive psychology supports this notion.

### Emotions

According to Darwin’s evolutionary theory, emotions are products of natural selection. Recurrent encounters with situations such as escaping predators, falling in love, or recognizing sexual

infidelity selected for adaptations that guided the processing of relevant information and response behavior. Over many generations, those emotions that contributed the most to individual fitness became more prevalent in the population. Modern day emotions are therefore well-designed for solving the adaptive problems of the ancestral environment. They are responses to probabilistic clusters of situational cues that were reliable enough to allow for such detectors to evolve. Situational cues trigger emotions, and with them, a perspective of seeing the world in a way similar to the ancestral cluster of situationally present elements.

The evolutionary theory of emotions states that situations relevant to emotions are those which recurred ancestrally, could not be handled successfully without a superordinate level of program coordination, had a reliable and rich repeated structure, had recognizable cues that signaled their presence, and in which an error would have resulted in large fitness costs (Cosmides and Tooby 2000). Emotions are viewed as superordinate programs which mobilize and direct subprograms such as goal planning, motivation and prioritizing, information-gathering, perception, memory, attention, physiology, communication and emotional expressions, behavior, specialized inference, reflexes, learning, effort allocation, and others. They detect evolutionarily reliable cues that a particular situation is occurring, and then activate a specific set of subprograms chosen as the most useful for dealing with that particular situation during the process of natural selection.

To identify an emotion as an adaptation, it is necessary to identify the adaptive problem, establish the evolutionarily recurrent situation in response to which an emotion has evolved, and describe cues that signal the presence of such situation, as well as situation-detecting algorithms (emotion programs), algorithms that assign priorities (i.e., a type of a supervisory system that decides on the order in which simultaneously arising situations should be dealt with), an internal communication system (sending a situation-specific signal to all relevant mechanisms), and algorithms that regulate responses to each

emotional signal (i.e., switching the mechanism on and off) (Cosmides and Tooby 2000).

Facial expressions associated with basic emotions served an adaptive function for the individual and their social surroundings. However, alongside the physiological function, emotion expressions also have a social-communicative function of, in the example of fear, a nonverbal warning of the other group members of an immediate threat. Expressions of emotions are highly recognizable, and in the case of the basic or primary emotions (happiness, sadness, fear, surprise, disgust, and anger), cross-culturally universal. While emotional responses of infants tend to be uniform, emotional expression of adults can be highly variable, due to a large number of open parameters on which emotional programs depend.

### Mate Choice

Mate choice or intersexual selection is an evolutionary process relating to the selection of a potential partner. Along with intrasexual selection, it is one of the two components of sexual selection. Modern humans' mate preferences are, from the perspective of evolutionary psychology, a result of evolutionary pressures and represent answers to adaptive problems associated with mate acquisition. These problems are often gender-specific, which means that the principles that apply to men do not necessarily apply to women. The consequences of this are the differing strategies of mate acquisition employed by the two sexes. The overarching reason behind these strategies may lie in the differential parental investments of women and men.

According to Trivers's *Parental Investment Theory*, parental investment is any parental expenditure that benefits an offspring and increases its chances of surviving at a cost of its parents' ability to invest in other aspects of their own fitness (Trivers 1972). Parental investment can be split into mating investment (i.e., the sexual act and the sex cells invested) and rearing investment (i.e., the time and energy invested into raising the offspring). One of this theory's main assumptions is that parental investment also affects sexual behavior. Reproduction is costly and each individual has limited time and resources available to produce

and raise their offspring. In regard to human reproduction and parental investment, a woman's investment in both mating and rearing the offspring surpasses that of the man. According to Bateman's principle of *Lifespan Reproductive Success* (LRS), the LRS variance is smaller in women due to their high obligatory parental investment. Women have a shorter reproductive life cycle than men, and their number of sex cells is much smaller. While men produce sperm cells at a rate of 12 million per hour, women are born with a finite supply of around 400 egg cells (Buss et al. 1992). Furthermore, both the fertilization and the 9-month-long gestation occur in a woman's body. After the birth, the woman is responsible for breastfeeding, and much like the pregnancy, lactation is a highly energy-demanding task. Since women are the more investing sex, evolution has favored those who are more selective of their mates. As a result, women are generally speaking more discriminating in choosing a partner.

Finding a partner involves using different *sexual strategies* – evolved solutions to adaptive problems associated with mate acquisition that have been faced by women and men during the evolutionary history of the human species. They are employed with no consciousness or awareness. According to the *Sexual Strategies Theory* proposed by David M. Buss and David P. Schmitt, there are two different types of reproductive strategies, which are used by both sexes: *short-term*, and *long-term*. While non-evolutionary psychologists sometimes still treat short-term mating as dysfunctional or even pathological, evolutionary psychologists consider both reproductive strategies to be adaptive. In order to understand human sexual strategies, it is necessary to consider evolutionary pressures that shaped them.

During the evolutionary history of the human species, both women and men have employed both the short-term and the long-term sexual strategies, depending on the conditions they were in. Either of the strategies solves different adaptive problems. Since the parental investment of women is disproportionately larger than that of men, women tend to allocate more effort in long-term mating. On the other hand, men invest more

in short-term mating than women do. There are many sex-related differences in both the reproductive opportunities and constraints in both contexts.

## Male Selection Pressures and Mate Preferences

From an evolutionary perspective, the reproductive success of men has been constrained by the number of available fertile women, as well as the difficulty of identifying the fertile women and women that are sexually accessible. Men employing a short-term sexual strategy encountered adaptive challenges of finding as many potential partners as possible, identifying women that were sexually accessible, and women that were fertile, while also trying to minimize their own risks, commitment, and investment. The main way in which men increased their reproductive success has been through an increase in the number of sexual partners. However, that approach carries many costs. The higher the number of women with whom a man achieves sexual contact, the higher is his risk of contracting a sexually transmitted disease. Another cost associated with high numbers of sexual partners is a gain of negative social reputation, which could impair a man's value as a potential long-term mate for women of high mate value, as such behavior signals a low likelihood of parental investment, an important preference to women looking for a long-term partner. Men employing long-term strategies were faced with challenges of identifying reproductively valuable women, women with quality genes, women with good parenting skills, and women who are willing and able to commit to a long-term mating relationship. The success in dealing with these problems presented them with a final problem of ensuring certainty in paternity.

Short-term strategies are more prevalent in men than women. As one of the main adaptive challenges men have faced is gaining sexual access to as many women as possible, they have evolved a strong desire for sexual access to a large number of women (Symons 1979). This trait is accompanied by employing comparatively lower

standards for what constitutes an acceptable short-term partner. Woman's age, intelligence, or personality are in this context of lesser relevance, and the time men are willing to invest before trying to obtain sexual contact is shorter. Men seeking a short-term mate are also likely to more intensely pursue women who are sexually accessible than those that are not. Promiscuity, although highly undesirable in a long-term mate, is likely to be desired in a short-term mate, as it signals accessibility. This implies a higher likelihood of discrimination against women with traits such as prudishness, sexual inexperience, conservativeness, or a lower sex drive.

Another adaptive problem men have faced is identifying women who are fertile. There are two different angles to tackling this challenge – assessing women's fertility and *reproductive value*. Fertility refers to the probability of present reproduction for a given age and sex, while reproductive value is the extent to which people of a given sex and age are likely to contribute, on average, to the ancestry of future generations (Fisher 1930). Female fertility typically peaks in the early to middle twenties, while their reproductive value is the highest in the middle teens (Thornhill and Thornhill 1983), and both show a steep decline with age. According to this, men seeking a short-term mate are more likely to prefer women of higher fertility, while those among them who are seeking a long-term mate should be more interested in their prospective partner's reproductive value. However, it is nearly impossible to know a person's fertility or reproductive value. Younger and healthier women are more likely to have higher reproductive capacities, but since age or health are also not always directly observable, men have evolved preferences for features that act as cues of a woman's age and health. Examples include physical characteristics such as facial symmetry, clear and smooth skin, clear eyes, full lips, shiny hair, and good muscle tone, as well as behavioral characteristics such as youthful gait or high activity level, and a woman's social reputation.

As a man's reproductive success depends on his number of sexual partners, one of the adaptive challenges men faced was avoiding commitment.

A large investment into a single partner meant fewer number of total partners. One of the answers to this problem is avoidance of women who desire long-term commitments.

Despite the many advantages of pursuing a short-term sexual strategy, men have also evolved long-term strategies. Prior to engaging in sexual intercourse, women seek out reliable signals of long-term commitment. Since men might fake the long-term interest, women have evolved psychological mechanisms to detect deception and mechanisms that allow a reliable prediction of actual long-term commitment potential. Additionally, women look for commitment signals that are more costly to forge, thus forcing men into long-term relationships. This has, however, brought benefits to men. Commitment to a single partner decreases the costs of repeatedly pursuing short-term mates, while increasing the opportunity for developing cooperative relationships, due to a mutual interest in the same children. This allows for more efficient care, decreasing the necessary effort per offspring. Willingness to dedicate all resources to one partner also increased men's chances of obtaining a partner of higher-quality phenotypic attributes or genes, which could later be passed down to their offspring (Gangestad 1989).

The main cost of pursuing long-term strategies is a decreased number of potential partners. By committing to a single long-term partner, men are jeopardizing their reproductive success. They therefore needed to find a way to maximize their reproductive success with a sole partner. Unlike many other mammalian species, women have a concealed (cryptic) ovulation. For men, this creates a problem of decreased certainty of paternity. As they cannot be sure when a woman is ovulating, formation of long-term relationships was selected for in men. Men who monopolized a woman during longer time periods gained a selective advantage by an increased probability of paternity of children conceived in that relationship. For this reason, men show a preference for women who provide them with evidence that, if the relationship results in offspring, their paternity will be certain. Traits such as faithfulness and sexual loyalty are highly preferred in long-term

mates, although they are seemingly irrelevant when it comes to the selection of short-term partners (Buss et al. 1992). Sexual jealousy is stronger in men than in women (Buss et al. 1992), and it evolved in response to the problem of paternity uncertainty. It elicits mate guarding, so as to decrease intrasexual competition and lower the likelihood of another man fathering an offspring.

### Female Selection Pressures and Mate Preferences

Reproductive success of women has been constrained not by the quantity of the available potential partners, as is the case with men, but by their quality. Mate quality is assessed in terms of the external resources that such union would bring the women and their shared offspring, as well as a man's genetic makeup. Within a short-term mating context, these constraints can be summarized as the problem of immediate resource extraction and the problem of assessing a man's genetic quality. As women are the more investing sex, the importance of selecting the correct long-term partner is higher, as is the cost associated with making the wrong choice. Because of this, women sometimes engage in short-term relationships to assess men as prospective long-term mates.

As women pursue short-term sexual strategies in a different way than men, they also desire different attributes in their short-term mates. However, some of the risks women are faced with are similar to those that are faced by men. By having multiple partners, women increase the risk of contracting sexually transmitted diseases, as well as being physically or sexually abused, in the attempts of men to control them reproductively. Short-term strategies may also impair their value as long-term partners. This is, however, more detrimental to women than it is to men due to the paternity certainty problem men have faced. As a result, the social status of sexually promiscuous women is likely to decrease. Women of high mate value tend to be more discriminating than women of lower mate value, which leads to promiscuity being regarded as an

indicator that a woman is not capable of securing a quality long-term mate (Buss and Schmitt 1993).

Women are less inclined to short-term strategies, but they still carry reproductive benefits (Gangestad 1989). For example, pursuing shorter relationships with high-quality mates that are not available for long-term relationships is a way for women to obtain better quality genes that can be passed on to their offspring, increasing their survival or reproductive success, as well as for women to obtain material resources. Beyond the obvious example of prostitution, which involves a direct exchange of resources for temporary sexual access, men bringing gifts to women whom they sexually engage with is a cross-culturally stable finding (Shostak 2014). Women who pursue short-term sexual strategies are more likely to show a preference for traits that signal immediate provision of resources, such as ambition, intelligence, industriousness, material possessions, lack of existing commitment, high income, and generosity. However, these characteristics are also desirable in prospective long-term partners.

Because women use short-term relationships as a way to assess potential long-term partners, their short-term preferences are much more similar to their long-term preferences than is the case with men. Although short-term encounters may provide women with better quality mates who would otherwise be inaccessible to them, they seek out long-term partners so as to ensure male parental investment. Social and economic benefits, such as high social status and provision of resources, are advantageous for the offspring. Furthermore, if traits that lead to acquiring better social status and more resources are heritable, mating with men who possess these features may also give the resulting offspring a reproductive advantage. Additionally, long-term partners may provide food and protection to the woman, which is especially important in periods when the woman is especially vulnerable, such as during pregnancy and lactation.

Pursuing a long-term sexual strategy does not limit women's reproductive success in the way that it does men's, as the number of potential offspring a woman can have in a given amount of time is restricted by her own biology, and not

her partner's. The adaptive problems women had to solve to pursue a long-term mating strategy have been identifying men who are able and willing to invest resources in both them and their potential children on a long-term basis, men with quality genes, men with good parenting skills, men who are able and willing to commit to a long-term mating relationship, and men who would be able to grant them and their children physical protection from aggressive conspecifics. Due to these differences, men and women have evolved distinct psychological mechanisms, to help them pursue short-term and long-term mating strategies.

Female sexual selection is evident from the sexually dimorphic phenotypic features that are selected for, but which would otherwise serve very little purpose, such as beards, lower voice pitch, and greater height. These are indications of good genes, which will be passed on to the offspring, increasing their chances of survival or reproduction. However, as male reproductive capacity declines less steeply with age and cannot be as accurately assessed from their physical appearance, characteristics that indicate reproductive capacity are comparatively less valuable to women than they are to men. Phenotypic traits' relative importance is therefore second to that of personality characteristics, social and financial status, which signal the likelihood of a successful and long-lasting relationship with a potential partner, as well as his ability to take care of offspring.

## Research Methods in Evolutionary Psychology

Evolutionary psychologists use several methodological approaches to test whether a particular psychological trait could be an evolved adaptation. The *Cross-cultural Consistency* approach focuses on the characteristics that were found to be universal across cultures, such as facial expressions. *Function to Form* ("Problem to Solution") direction of analysis is used when the psychological mechanism is known, and an attempt is made to discover its evolutionary benefit – for example, gender differences in sexual versus emotional jealousy (with the former being more

characteristic of men, while the latter is more typical of women) thought to originate in men's higher risk of misidentification of offspring (the so-called "paternity insecurity"). The reversed, *Form to Function* ("Solution to Problem") approach is used when some behaviors or traits seemingly carry the characteristics of adaptations. For example, women's morning sickness during pregnancy and aversion to certain types of food are both complex and universal, and have been hypothesized to have the function of avoiding the ingestion of toxins that could damage the fetus (but would be harmless to nonpregnant women). *Corresponding Neurological Modules* approach combines evolutionary psychology and neuropsychology. The former is used to identify the ultimate evolutionary functions of psychological mechanisms regarded as adaptations, while the latter helps identify their proximate manifestations. The *Current Evolutionary Adaptiveness* approach is used to study the impact of psychological adaptations in the current environment. This type of research can be useful in studying evolutionary psychopathology. Evolutionary hypotheses can be tested experimentally, in observational studies, using archaeological records, neuroscience data, self-reports and surveys, public records, mathematical models, or using computer simulations.

## Criticism of Evolutionary Psychology

One of the main critiques of evolutionary psychology is the problem of testability of evolutionary hypotheses. Some of the hypotheses are very difficult or even impossible to test, which challenges the discipline's status as an empirical science. Many traits considered to have been adaptive in the EEA now serve different functions, and they can frequently be explained by entirely opposite hypothesis, as often the only evidence for their adaptiveness is their own internal logic. Moreover, many traits originally considered universal have later been found to be culturally dependent or products of historical circumstances. Evolutionary psychologists are often accused of ethnocentrism, and of believing that their own current cultural context is representative of

universal human nature. However, their main defense is that they are simply focusing on commonalities rather than variation, in order to help identify cultural universals.

Many evolutionary hypotheses are criticized for being based in the assumptions made about the EEA, of whose features there is often insufficient evidence. Evolutionary psychology assumes that the EEA was uniform, but critics contend that it is possible that there were multiple EEAs, which makes presumptions about specific traits' adaptiveness unsubstantiated (Plotkin 2008). A counterargument to this critique states that although a lot of information about the EEA is missing, considerable information about the lives of ancestral humans and the environment in which they lived is available, and hypotheses are only made regarding psychological mechanisms related to those certainties, for example, kinship, female-exclusive pregnancy and lactation, cooperation in hunting and predator avoidance, and others (Buss 1999).

Evolutionary psychologists are at times criticized for reductionism and genetic determinism, as well as limiting environmental influences to that of a trigger, or a predetermined developmental instruction encoded in the genes. According to the critics, evolutionary psychology has trouble differentiating between cultural and environmental explanations on the one side, and adaptive, evolutionary explanations on the other, which leads to a discrediting of social processes, cultural artifacts, and dialectical explanations. A counterargument to this claim lies in the historical importance of reductionism to many scientific discoveries, as well as the importance of assessing different phenomena on all levels, including that of genes and environmental pressures. Moreover, while genes do not cause behaviors, they predispose for them, allowing other, external factors to further affect their expression.

## Definition

Behaviors exchanged between individuals belonging to the same group or society.

## Introduction

A particular feature of primate species is that most of them live in groups or societies. Within these societies, individuals do not seem to interact at random with other group-members; instead, they appear to selectively interact more with some individuals than with others. Further, the type of social behaviors display towards group members may differ depending on the identity of a given individual. This arrangement of social interactions gives rise to complex patterns of social behavior. For instance, in many primate societies, individuals appear to exchange social behaviors, e.g., grooming for the receipt of support in fights. The exchange of social behaviors has been extensively studied during the last 30–40 years. Empirical support for the exchange of behaviors comes mainly from studies that usually find a statistically significant positive correlation between the number of behavioral acts given and the ones received. These studies usually distinguished between the

exchange of the same kind of behaviors (hereafter reciprocity) or between different kinds (hereafter interchange). This entry revises studies on behavior exchange in species of great apes and New and Old World monkeys. It is focused on these taxa, given the great amount of research that has been conducted on them. It will start by defining the three main types of social behaviors being exchanged in primate societies. Then, it will review the evidence that has been accumulated during the last 30–40 years, supporting the exchange of behaviors. Thereafter, it will focus on the ultimate functions and proximate mechanisms that gave rise to the exchange of behavior. Lastly, it will address the biological market theory.

## Behaviors Exchanged

Three behaviors have usually been the focus of studies investigating reciprocation and interchange of behaviors in societies of primates: allo-grooming, support in fights or coalitions, and food sharing.

Grooming is possibly the most common behavior in primates. It is defined as the brushing and picking at the hair of the fur. Grooming can be self-directed (auto-grooming) or directed towards another individual's fur (allo-grooming). Allo-grooming (hereafter grooming) is thought to serve many different functions such as hygienic, reduction of tension, establishment and maintenance of social bonds, etc. Grooming thus is considered a valuable commodity for primates, and it may be used as a currency to exchange for itself or other commodities (Henzi and Barrett 1999).

Support in fights or coalitions are defined when one individual intervenes in an ongoing conflict between two opponents and supports one against the other (Schino 2007). Following this definition, this kind of social interactions are triadic with the intervening individual being the “supporter,” the individual being helped the “recipient of support,” and the individual being attacked the “target of aggression.” Coalitions with more than three participants have also been described. Studies on interchange of support, however, have usually focused on triadic interactions.

Food sharing is defined as the transfer of food from one individual, “the possessor,” to another, “the recipient.” Food sharing can be passive, the possessor allowing the recipient to take pieces of food, or active, in which the possessor actively hands a piece of food to the recipient (Gilby et al. 2010). The vast majority of food sharing in primates is passive, i.e., above 95% of the instances in which food sharing has been recorded (Jaeggi and Van Schaik 2011).

## Exchange of Same Type of Behaviors: Reciprocity

Reciprocity of grooming and support has been commonly reported in primate societies. The evidence for the exchange of grooming given, for that of grooming received, is compelling. A meta-analysis that included 48 different primate groups belonging to 22 species and 12 genera (Schino and Aureli 2008a) found that individuals directed more grooming to those from whom they also received more grooming, i.e., grooming was reciprocated. Similarly, many studies have reported a significant positive correlation between the amount of support given in fights and that received. In a review on support in fights, Smith et al. (2010) found that individuals gave more support in fights to those from whom they also received more support, in 61% of the studies revised (19 out of 31 studies). In contrast, evidence for reciprocity of food sharing is scarce among monkey species; perhaps due to the fact that food sharing outside the mother-offspring context is not a common behavior in monkeys (Jaeggi and Gurven 2013). Only studies on capuchin monkeys (*Cebus apella*) have reported significant positive correlations between the acts of food given and those received (de Waal 2000). Regarding great apes, most studies on food sharing have focused on chimpanzees (*Pan troglodytes*). In this species, individuals indeed seem to reciprocate food sharing (Boesch and Boesch-Achermann 2000; de Waal 1997; Mitani 2006; Silk et al. 2013). The few studies on bonobos (*Pan paniscus*) (Goldstone et al. 2016; Jaeggi et al. 2013) and orangutans (*Pongo* sp.) (Kopp and

Liebal 2016; van Noordwijk and van Schaik 2009) on the other hand have found no evidence for reciprocation of food sharing.

## Exchange of Different Types of Behaviors: Interchange

### Interchange of Grooming

Studies on the interchange of grooming have mostly focused on the correlation between grooming given and support in fights received and vice versa, support in fights given and grooming received. Evidence for this kind of interchange is moderate. In their review on support in fights, Smith et al. (2010) report that ~53% of the primate studies revised present evidence for the interchange of grooming and support, and in a meta-analysis of 36 primate studies from 14 different species, Schino (2007) found a weak but significant positive correlation between grooming and agonistic support. Further, in studies on different groups belonging to the same primate species, evidence has been found for some groups but not for others.

Besides being interchanged for support, grooming seems to be interchanged for some other behaviors as well. For instance, Tiddi et al. (2012) found that individuals interchanged grooming for tolerance during feeding time in wild tufted capuchin monkeys (*Cebus paella nigrinus*). Other studies have found an interchange between grooming and access to handle infants (e.g., chacmababoons, *Papio cynocephalus ursinus*, (Henzi and Barrett 2002)). Further, a study by Gumert (2007) found that male long-tailed macaques interchange grooming for sex with females. Moreover, several studies on macaques (Puga-Gonzalez et al. 2016; Schino et al. 2005) have found a positive correlation between aggression given and grooming received, a finding interpreted as an extortion of grooming (Schino et al. 2005).

### Interchange of Food

Reciprocity and interchange of food outside the mother-offspring context has rarely been reported in species of primates other than great

apes (Jaeggi and Van Schaik 2011). Thus, the focus below is on studies investigating interchange of food in great apes and especially on chimpanzees.

Chimpanzees are frequent hunters, male chimpanzees have been regularly observed to prey on monkeys (e.g., red colobus – *Procolobus* spp.) and other small mammals, and they often share the meat obtained from these hunts (Gilby et al. 2010). Besides sharing meat, chimpanzees also share other types of food such as plants or fruits, although to a lesser extent than meat. Several interchange-based hypotheses have been put forward to explain this kind of behavior. Food for grooming, food for support, and food for sex are usually invoked as an explanation. Others, however, suggest that food sharing has nothing to do with interchange. Instead, they suggest that chimpanzees share food to reduce begging/harassment from other group members, i.e., the “sharing under-pressure” hypothesis. According to this hypothesis, food sharing is a form of tolerated theft.

Some of the best evidence for the interchange between food and grooming comes from studies by Mitani and colleagues (Mitani 2006) on chimpanzees’ communities at Ngogo, Kibale National Park in Uganda. Studies on these communities have been carried out several times over a time span of over 4 years. In all cases, researchers have consistently found positive correlations between food shared and grooming received and vice versa. It seems thus that individuals in these communities interchange food for grooming. Further evidence comes from experimental studies on captive chimpanzees at the Yerkes National Primate Research Center, USA, in which it was shown that individuals were more likely to share food with others after being groomed (de Waal 1997). Studies on chimpanzees’ communities of Gombe in Tanzania, however, have failed to find evidence of the trade between food and grooming (Gilby et al. 2010). Regarding the interchange between food and support, studies on communities of wild chimpanzees at Ngogo and at Tai National Park in Cote d’Ivoire have found positive correlations between these two behaviors (Mitani 2006). Hence, in these communities,

individuals appear to share more meat with those from whom they received more support in fights.

Most research on the interchange of food has focused on the interchange of food for sex. In chimpanzees, males are the usual hunters and are often observed to share meat with females. Thus, it has been hypothesized that, as in human hunter-gatherer communities, males chimpanzees may trade meat for sex with females (Gomes and Boesch 2009). Evidence in support of this hypothesis is, however, mixed. Initial studies suggested that the presence of estrus (fecund) females in the group influenced the motivation of male chimpanzees to hunt (Sánchez-Amaro and Amici 2015). More recently Hockings et al. (2007) showed that when chimpanzees raided crops, males were more likely to share their food with a cycling female; Gomes and Boesch (2009) found that males who shared meat with females increased their mating opportunities with them in the long-term but not in the short-term. In contrast, several other studies have failed to find evidence in support of the “food for sex” hypothesis. For instance, Hemelrijk and colleagues found that sharing food was not correlated with the probability of copulating (Hemelrijk et al. 1992), nor with siring offspring with a specific female (Hemelrijk et al. 1999). And Gilby et al. (2010) found that Gombe males were not more likely to share food with estrus than with anestrus females, that the presence of estrus females did not increase the probability of hunting, and that sharing meat with females did not increase the probability of mating in the short-term. Gilby and coauthors (Gilby et al. 2010) thus have suggested that meat sharing in chimpanzees is better explained by the sharing under-pressure hypothesis. The sharing under-pressure hypothesis suggests that individuals share food in order to stop the harassment of other group-members begging for food around them (Gilby et al. 2010). Several studies have indeed found a correlation between the amount of begging received and the amount of food shared (Silk et al. 2013). In sum, evidence supporting the “food for sex” hypothesis remains circumstantial at most.

Few studies have investigated food sharing in other great ape species. In contrast to

chimpanzees, bonobos and orangutans share primarily fruit. Studies that focused on these two great ape species have found little evidence in support of the “food for grooming,” “food for sex,” or “sharing under-pressure” hypotheses (Goldstone et al. 2016; Jaeggi et al. 2013; Kopp and Liebal 2016; van Noordwijk and van Schaik 2009). Instead, researchers suggested that bonobos share food with those with whom they have a good relationship (Jaeggi et al. 2013; Kopp and Liebal 2016), and that individuals may beg for food, to gain information about the aggressiveness or relationship status with the food possessors (Goldstone et al. 2016; van Noordwijk and van Schaik 2009).

## Ultimate Causes of Behavior Exchange

When an individual displays altruistic behaviors (a behavior that provides a benefit to the recipient, while incurring a fitness cost to the actor), it is thought that the actor must somehow receive a benefit in return; otherwise, natural selection would not have allowed the evolution of such behaviors. Grooming, support in fights, and food sharing, are behaviors considered altruistic, and thus, if individuals display these behaviors towards others, it is because they also obtain a benefit (de Waal and Brosnan 2006). Evolutionary theory suggests that altruistic behaviors can evolve via two different processes: kin selection or reciprocal altruism. According to the kin selection theory, altruistic behaviors may evolve, when actors direct their altruistic behaviors towards their own kin because by helping their kin, they increase their own inclusive fitness (Hamilton 1964). Hence, altruistic behaviors are expected to occur mostly among kin-related individuals. Reciprocal altruism on the other hand suggests that altruistic behavior may evolve even if individuals direct beneficial behaviors towards nonkin-related individuals. In this case, however, individuals should restrict their altruistic acts to those, from whom they are certain to receive an altruistic act in the future, i.e., altruism must be reciprocated. In this way, the fitness of altruistic individuals is increased (Trivers 1971). Indeed, as

suggested by both theories, in many primate studies, it has been shown that altruistic behaviors such as grooming, support in fights, and food sharing are usually directed towards kin-related individuals (Jaeggi and Van Schaik 2011; Schino 2007; Schino and Aureli 2008a). Further, in studies in which the effect of kinship could be controlled, individuals still directed more altruistic acts towards those from whom they also received altruistic behavior (Mitani 2006; Schino 2007; Schino and Aureli 2008a). It seems, thus, that kin selection and reciprocal altruism have played a key role in the evolution of behavior exchange in primate societies.

### Proximate Mechanisms of Behavior Exchange

The proximate mechanisms underlying reciprocity and interchange of behaviors are still controversial. Three mechanisms, varying in their degree of cognitive demands, have been proposed: symmetry-based reciprocity, attitudinal reciprocity, and calculated reciprocity (de Waal and Brosnan 2006).

Symmetry-based reciprocity is the mechanism requiring the least cognitive capacity. This mechanism assumes that positive correlations between behaviors given and received may result from a common symmetrical variable within a dyad of individuals, e.g., proximity, kinship, age, and rank. For instance, when individuals direct most of their behaviors towards those partners with whom they spent most in proximity or to those of similar age or rank, reciprocation and interchange should automatically emerge (de Waal and Brosnan 2006). Symmetry-based reciprocity, however, seems insufficient because when symmetrical variables are removed from the correlations, the correlations remain still statistically significant (Gomes and Boesch 2009; Mitani 2006; Schino 2007; Schino and Aureli 2008a). This suggests that reciprocity and interchange are not entirely explained by symmetry in common variables between dyads, and that other mechanisms must underlie the behavior exchange.

Calculated reciprocity is the mechanism requiring the most sophisticated cognition. This mechanism assumes that, to avoid being cheated, individuals keep track of the number of behaviors given to and received from each group member, respectively. Hence, it requires long-term memory of past events (de Waal and Brosnan 2006). Calculated reciprocity has been criticized because keeping track of acts given and received over the long-term is a task that is difficult, even for humans (Stevens et al. 2011). Therefore, several studies have investigated whether reciprocation and interchange of behaviors occur on a short-term rather than on a long-term basis. These studies, however, did not find evidence of short-term reciprocity or interchange (Amici et al. 2014; Gilby et al. 2010; Gomes and Boesch 2009; Jaeggi et al. 2013). The lack of evidence for short-term reciprocity and interchange has shifted the focus from “calculated reciprocity” to more parsimonious mechanisms, such as “attitudinal reciprocity” (de Waal 2000) or “emotional book-keeping” (Schino and Aureli 2009).

Attitudinal reciprocity was first proposed by de Waal (2000) as a mechanism mediating food sharing reciprocity in brown capuchin monkeys (*Cebus apella*). He suggested that individuals may reciprocate behaviors by mirroring the attitudes of their social partners in recent interactions, i.e., “if you are nice, I’ll be nice” (de Waal 2000). This idea was then further developed by Schino and Aureli (2009) to explain reciprocity and interchange of behaviors over the long-term. They proposed emotions as the basis of the individuals’ behavioral decisions. Whether an individual reciprocates or interchanges a behavior with a specific partner depends on the type of emotion the individual associates with that partner. The frequent receipt of beneficial behaviors (e.g., grooming) from a specific partner over long periods of time elicits the association of a positive emotion with that partner. This emotion may then subsequently motivate the individual to behave positively towards this specific partner as well (Schino and Aureli 2009). Emotions, thus, enable individuals to preferentially interact with those group members that have provided them with most benefits over a long-term period, rather

than on a short-term basis (Schino and Aureli 2009). This mechanism, called “emotional book-keeping,” is nowadays the leading hypothesis regarding the proximate mechanism giving rise to reciprocity and interchange of behaviors. Indeed, several empirical studies have shown that individuals reciprocate and interchange behaviors in the long-term rather than in the short-term, and that they do so with those partners, with whom they form long-lasting “social bonds” (Gilby et al. 2010; Jaeggi et al. 2013; Kopp and Liebal 2016; Silk et al. 2013).

### Biological Market Theory

Biological market theory attempts to explain not only how individuals exchange behaviors but also the variation in the degree of exchange. In some primate societies, researchers have consistently found a correlation between grooming given and the individuals’ dominance rank, i.e., individuals direct grooming up the dominance hierarchy. To explain this finding, Seyfarth (1977) reasoned that individuals use grooming as a “currency” to interchange for the receipt of support in fights and because individuals ranking high in the dominance hierarchy offer the best support, individuals should aim at interchanging grooming for support with them. Individuals, thus, should direct their grooming toward high ranking individuals. In some societies, however, the correlation between grooming given and dominance rank is either weak or absent, and in other societies, agonistic support is rare or absent but individuals still direct grooming up the hierarchy (Sánchez-Amaro and Amici 2015). Thus, to explain the differences in the distribution of grooming behavior observed in groups and species of primates, Henzi and Barrett (1999) introduced biological market theory into the primates’ social system.

Nöe and Hammerstein (1994) developed biological market theory to explain how individuals trade commodities in any given biological system. The theory assumes that whenever commodities cannot be acquired by force and are under the control of individuals, individuals may interchange commodities for their mutual benefit.

The theory assumes that, similar to human markets, in any given biological market there are two classes of individuals, producers and consumers; it also assumes that the rate of exchange of commodities is determined by the laws of supply and demand, i.e., when the commodity offered is rare, its value (and price to pay) should be higher than when it is common (Nöe and Hammerstein 1994). The theory, thus, assumes that individuals are able to choose trading partners according to the type of commodities they offer and the current rate of exchange. Henzi and Barrett (1999) extended this theory into primate societies. They argue that in primate societies, grooming is a valuable commodity that can be either traded for itself or for other commodities. If the dominance hierarchy in a primate society is steep, high-ranking individuals are able to monopolize resources; and in this case, subordinates may benefit by trading grooming for rank-related benefits, e.g., support, tolerance, food, etc. In shallow hierarchies, on the other hand, resources cannot be monopolized and, consequently, high-ranking individuals have no commodities to trade for. In this case, grooming would be exchanged only for itself, i.e., reciprocated. Grooming directed up the dominance hierarchy should then be expected when the dominance hierarchy is steep, but not when it is shallow (Henzi and Barrett 1999).

Several studies hinted at the operation of biological market theory in primate societies. For instance, in a meta-analysis on grooming reciprocation, Schino and Aureli (2008b) found that primate groups with steeper dominance hierarchies were associated with a higher tendency to groom up the dominance hierarchy and a lower degree of grooming reciprocation. Similarly, Barrett et al. (2002) studied a troop of Chacma baboons (*Papio ursinus*), in which the competitive regime differed at two different time periods. In period one, when the dominance hierarchy was steeper than in period two, the degree of grooming reciprocation was lesser than in period two. This finding was interpreted in support of biological market theory, arguing that individuals in these societies adjust their distribution of grooming to the fluctuation in the competitive regime of the group. Perhaps the best evidence in support of

biological market theory comes from an experimental study on two groups of wild vervet monkeys (*Chlorocebusaethiops*) by Fruteau et al. (2009). In their experiments, researchers first taught an individual to open a food device and provide food to its group members. Then, they measured the amount of grooming the food provider received in the hour after food was provided. In a second step, they taught another individual to open a second food device and provide food to others. Again, they measured the amount of grooming received by the food providers. Their findings showed that food providers received more grooming after being taught to manipulate the device and provide food to others, than at baseline levels. More interestingly, the amount of grooming the first provider received decreased after the introduction of the second food provider, but, nevertheless, this amount remained still higher than the baseline levels. The authors concluded that, as suggested by biological market theory, in these groups, grooming was fine tuned to the laws of supply and demand (Fruteau et al. 2009).

Despite these results, some researchers are skeptical about biological market theory. In a recent review, Sánchez-Amaro and Amici (2015) identified several issues, which according to them, need to be addressed to firmly confirm that primates trade behaviors as suggested by biological market theory. A first issue is that in all studies on behavior exchange, the time frame of interchange is undefined. Experimental studies find that individuals may interchange grooming for food within periods of 1–2 h (de Waal 1997; Fruteau et al. 2009). Observational studies on the other hand, find that interchanges happen in the long-term. Chimpanzees, for instance, reciprocate grooming and interchange meat for sex over periods that span up to 15–22 months, respectively (Gomes and Boesch 2009). This raises questions such as why primates interchange some behaviors in the short-term and others in the long-term? What is the biological significance of this? Is it valid to use different time frames across different studies/populations of primates (Sánchez-Amaro and Amici 2015)? Another

issue is the type of behaviors being exchanged. Grooming is usually thought to be the “currency” to be exchanged for several other behaviors. Thus, how do individuals know what grooming is being interchanged for (itself, food, support, etc.)? Similarly, how can researchers know what grooming is being exchanged for? (Sánchez-Amaro and Amici 2015). All these questions need to be answered, so that careful predictions can be formulated and tested with empirical data. Finally, besides the cognitive challenges previously identified (e.g., keeping records of behaviors given and received), there are some other cognitive skills that seem necessary for the biological market theory to be plausible. Individuals, for instance, should be capable to assess the number of producers and consumers in their group over time and adjust the relative value of the behavior being interchanged according to laws of supply and demand. Whether primates have the cognitive skills to do so or whether emotional bookkeeping can account for these, complex interchanges remains to be investigated (Sánchez-Amaro and Amici 2015).

## Conclusion

There is good correlational evidence that individuals in primates’ societies reciprocate and interchange different kind of behaviors (grooming, support in fights, food). It also seems likely that evolutionary processes such as kin selection and reciprocal altruism may have given rise to behavior exchange in primate societies. It remains unclear, however, what the proximate mechanisms underlying interchange and reciprocation of behaviors are, and whether these interchanges operate as predicted by biological market theory.

## Excretory System

Shane Peters

Hofstra University, Hicksville, NY, USA

## Introduction

The excretory system is a vital biological system that removes excess and waste products from the body to maintain ► [homeostasis](#). Most of these products are in fact used and broken down components of metabolism that leave the body in the form of urine, sweat, or feces. While many organs are linked indirectly to the removal of metabolic waste, the term excretory system refers to those organs that are used strictly for the elimination and excretion of these broken-down components; this limits the focus of a discussion of the excretory system to mainly the urinary, or renal, system, which consists of the kidneys, ureters, a bladder, and a urethra. While there is a specific set of organs generally referred to as the excretory system, there are several auxiliary organs that play roles in other major body systems that help in the excretory system's function.

## The Central Role of the Kidneys in the Urinary System

The excretory system is largely associated with the urinary, or renal, system. This system consists of various organs that produce and then excrete the urine out of the body: the kidneys, ureters, the bladder, and the urethra. While many might assume that the urinary systems of males and females are incredibly different, they are in fact largely the same; the major difference between the two genders is the length of the urethra. The system has multiple functions: to eliminate metabolic waste matter, to regulate the pH of the blood, to regulate blood pressure and volume, and to control the levels of metabolites and electrolytes such as sodium, potassium, and calcium (Marieb and Hoehn 2001). To put it succinctly, urine is

formed in the kidneys and travels through the ureters to be stored in the bladder until it is expelled from the body through the urethra.

To begin the process of urine formation, the two kidneys remove nitrogenous wastes from blood that is supplied from the renal arteries. The right and left renal arteries are blood vessels that transport blood flow in the body into the kidneys (Fine and Keen 1966). Each artery splits into multiple branches before reaching the hilum, which is the center region of the kidney that recesses into itself. The renal veins drain the kidneys of blood after it has been filtered and send it through to the inferior vena cava. The inferior vena cava carries deoxygenated blood from the lower and middle body into the right atrium of the heart (Saladin 2007).

The basic functional unit in the kidney is known as the nephron, which acts as a filter and regulates water concentration and soluble substances such as sodium, filters blood, and controls the pH of blood (Jones et al. 2013). The kidney contains a varied range of nephrons from 500,000 to nearly two million nephrons in humans (Douglas-Denton et al. 2006). A glomerulus capillary and the Bowman's capsule lie where the nephron begins at the renal corpuscle. An afferent arteriole, basically a small blood vessel leading towards the glomerulus, supplies the glomerulus with blood. Because the efferent arterioles that lead away from the glomerulus are narrower than the afferent vessels leading towards the glomerulus, a hydrostatic pressure gradient is created that helps force water and solutes in the blood to be filtered into the Bowman's capsule. The afferent arteriole has a higher blood pressure, while the efferent arteriole has a lower blood pressure (Marieb and Hoehn 2001; Jones et al. 2013; Saladin 2007). The membrane is impermeable to larger molecules such as proteins (Marieb and Hoehn 2001).

The filtrate travels into the renal tubule and then into the collecting ducts. In the collecting ducts, the normally water impermeable duct becomes permeable due to antidiuretic hormones, or ADH, that affect aquaporins, membrane proteins that facilitate water transport while preventing passage of other solutes. ADH

leads to the reabsorption of water through osmosis. Osmosis occurs when the concentration of a solute is higher in one region than it is in another; solutes go down the gradient into the region with a lower concentration to equal out (Nielsen et al. 2002). Solute in the filtrate, such as water, glucose, amino acids, and other ions like sodium, are reabsorbed by nephrons, excreting what is not needed as urine. Excess water and nitrogenous waste products such as urea, uric acid, and creatinine are not reabsorbed (Marieb and Hoehn 2001). This means that antidiuretic hormones control the concentration of urine. During dehydration, ADH levels increase when the individual is dehydrated to retain water. Conversely, ADH levels decrease when the individual has had plenty of water, leading to the dilution of urine. Urine leaves these collecting ducts into the renal calyces and then the renal pelvis on its way into the urinary bladder (Marieb and Hoehn 2001).

The renal pelvis is at the mouth of the ureter and acts as a funnel to flow urine into the ureter, collecting urine from the surrounding renal calyces (Marieb and Hoehn 2001). The calyces are chambers of the kidney; urine travels from the kidneys into minor calyces that come together to form a major calyx. The walls of the calyces all lined with smooth muscle fiber that undergo peristalsis, or rhythmic constriction and relaxation to create wavelike movement that pushes the urine through the renal pelvis into the ureters to the bladder (Longrigg 1975; Saladin 2007). Urine is stored in the bladder and then released through the urethra in a process known as urination (Saladin 2007).

## Kidney Stones

When substances that normally dissolve in urine do not, they can build up and form kidney stones composed of calcium, cysteine, oxalate, and uric acid that normally do dissolve in urine. Kidney stone classification is determined by their location of ► [occlusion](#) or their compositional makeup. When they are in the kidney, they are referred to

as nephrolithiasis, in the ureter they are called ureterolithiasis, and in the bladder, they are called cystolithiasis. Kidney stones get stuck in the urinary tract but are usually small enough to pee out. Sometimes, however, the kidney stones get lodged in the ureter and begin to grow even more. The larger a stone becomes, the less likely it is to pass through the urine spontaneously (Stoller and Meng 2007). This can cause great discomfort and pain as it blocks the flow of urine. The excruciating pain that people experience when they do not pass through the urine stream due to their large size can last up to an hour as the ureter contracts and relaxes to push the stone out. It can also cause nausea or vomiting (Coe et al. 2005).

A urologist often treats kidney stones with shock wave lithotripsy, a procedure that involves using a laser to shock the large kidney stone into several smaller pieces that can be more easily urinated (Stoller and Meng 2007). Major risk factors are obesity, high fructose consumption, dehydration, and a surplus of calcium, oxalate, sodium, and animal protein in the diet (Romero et al. 2010). The pH of urine is an underlying factor that can cause supersaturation of urine. Supersaturation occurs when the urine contains more solvents than it can hold, resulting in buildup. Once nucleation, when molecules begin to stick together and crystalize, has begun, it begins to form much quicker. There is heterogeneous and homogenous nucleation. Heterogeneous nucleation requires less energy because it involves an existing surface on which to grow, while homogenous nucleation of a kidney stone must grow in the urine alone. For kidney stones formed due to uric acid or cysteine, the pH of urine plays a larger role than for calcium-based stones. As the pH of urine decreases, the solubility of uric acid in urine decreases as well (Coe et al. 2005). A higher solubility means something dissolves more easily; in this more acidic environment, the lower solubility means that uric acid begins to accumulate and solidify much easier in urine. Kidney stone prevention can involve alkalinizing agents to raise urine pH to over 6.5 to avoid the formation of stones (Worcester 2002).

## The Liver

The liver performs a variety of vital functions. It produces bile, which is secreted into the small intestine to emulsify fat and promote digestion. It performs various tasks in carbohydrate metabolism, such as the creating and storing glucose in glycogen until needed. With regards to excretion, the liver metabolizes amino acids and converts the ammonia that results into urea, which is a nitrogenous waste, found in urine (Saladin 2007). In birds, the liver also excretes uric acid, the white pasty substance that can be seen in the excrements of birds (Kotz et al. 2008). The liver excretes excess cholesterol and calcium using bile. In addition, the liver can detoxify alcohol, antibiotics, and other drugs. Bilirubin is metabolized from red blood cell breakdown and excreted as bile pigments as well (Saladin 2007).

## The Role of the Large Intestine in the Gastrointestinal Tract

When many people think of the excretory system, they do not always picture the urinary system. For many people, the excretory system is largely embodied by the role of the large intestine, which mainly absorbs water. The large intestine, also known as the large bowel, consists of the cecum, colon, rectum, and the anal canal. It makes up the final part of the gastrointestinal tract and is around 5 ft long. The gastrointestinal tract is responsible for food digestion and the extraction and absorption of energy and nutrients. The remaining waste is removed as either feces or urine, so the gastrointestinal tract is closely linked to the excretory system (Saladin 2007).

The ► **digestive system** is comprised of the mouth, esophagus, stomach, and the large and small intestines. This entry focuses on the gastrointestinal tract, a term which refers to small and large intestine, due to the more direct role in excretion these organs play. The small intestine is an organ that absorbs digestion products like carbohydrates, proteins, and vitamins into the bloodstream. It comprises three sections that in order are called the duodenum, the jejunum, and

finally the ileum. In the first section, the stomach's contents, pancreatic juice and bile secreted from the liver are mixed. The pancreatic juice neutralizes stomach acid, while the bile emulsifies fat. The jejunum is where most digestion and nutrient absorption into the bloodstream occurs, while the rest continue to the ileum (Saladin 2007). The ileum absorbs vitamin B12, bile acids, and other nutrients that remain in the waste product as it continues to the large intestine (Van der Heide 2016).

The large intestine's cecum starts attached to the small intestine's ileum. As it ascends into the abdomen and then moves laterally to the other side of the abdominal cavity, it is referred to as the colon and then the transverse colon. The transverse colon then descends, forms an S-shape known as the sigmoid colon, and turns into the rectum and then to the anal canal. The lower region of the large intestine extracts usable water from the waste before it is removed as solid brown feces during defecation. The large intestine neither produces nor contains digestive enzymes, as digestion is completed in the small intestine. The brown color comes from a compound called urobilinogen (Saladin 2007). A pigment urochrome is the cause of the yellowish tint of urine (Marieb and Hoehn 2001).

The first section of the colon contains the cecum and the appendix and is involved in digestion. The ascending colon is attached to the cecum and is responsible for removing water and recycling nutrients from waste material as it leaves the small intestine (Saladin 2007). Peristalsis is responsible for pushing waste material up towards the transverse colon that runs latitudinal to where it turns by the spleen. At this point, fecal matter is largely liquid due to the immense secretions during digestion, but as the waste material moves forward the excess water is extracted and the fecal matter begins to solidify as it moves towards the descending colon for storage. The sigmoid colon is S-shaped and connects the descending colon to the rectum. Lined with muscle, the walls of the sigmoid colon contract and move the stool into the rectum that holds it until defecation through the anus (Saladin 2007).

Once again, peristalsis is the method of transportation in the process called defecation (Saladin

2007). Frequency of defecation can vary from a few times daily to a few times weekly. Waste fills the rectum and encounters mucosa in the lower rectum, acting as a signal that it is time to defecate. When humans feel a need to defecate, it is because of rectal muscles contracting reflexively, the internal anal sphincter relaxing, and the external anal sphincter contracting (Biggs and Dery 2006; Nurko and Zimmerman 2014). The internal anal sphincter is an involuntary muscle that is nearly always contracted to prevent the leakage of waste matter. Fecal matter enters the anal canal when the internal sphincter relaxes as the rectum shortens due to peristaltic waves that push the feces out, and the external sphincter contracts to defecate (Shafik 1987; Penninckx et al. 1992). If an individual does not defecate in a timely manner, reverse peristalsis moves the waste product back into the colon where even more water is absorbed. As expected, prolonging defecation can lead to feces hardening, resulting in constipation (Nurko and Zimmerman 2014). Diarrhea occurs from the opposite, when people defecate waste material too fast and excess water has not yet been reabsorbed (Saladin 2007).

When people expel solid waste, it has been noted that urination often occurs simultaneously, despite being involved in two separate processes with separate organs. This is because the anal and urethral muscles are linked and can only contract together. When the external sphincter muscles relax during defecation, the urethral sphincter relaxes as well, releasing urine from the bladder. Normally, both the internal and external urethral sphincter is contracted, sealing the urethra and preventing urination. The internal urethral sphincter is a smooth muscle that is under involuntary control and is responsible for inhibiting urination. The external sphincter is made up of skeletal muscle, allowing for voluntary control over urination (Marieb and Hoehn 2001; Saladin 2007).

The large intestine plays another minor role of excretion but of the third phase of matter. While feces embody solid waste and urine expels liquid waste, the bacteria present in the large intestine help produce gaseous waste. Flatus, the gas that is generated in the intestinal tract because of bacterial activity, can contain gases such as

nitrogen, carbon dioxide, methane, hydrogen, and hydrogen sulfide (Calloway et al. 1966).

## The Skin and Sweat Glands

Sweat glands excrete sweat throughout the body to help cool the body when it gets warm in a process called perspiration. Sweat is therefore another form of waste, and it tastes salty because of the presence of sodium chloride, or NaCl, a salt that helps in evaporation (Saat et al. 2005). Sweat is a dilute electrolyte solution that also contains mainly water but also urea, fatty acids, lactic acid, proteins, and various other components (Draeos 2011).

In humans, the release of sweat helps to regulate levels of salt as well as to remove urea from the body (Huang et al. 2002). In reabsorption, sodium and chlorides pass through ducts such as a Na/K ATPase pump or the chloride channel cystic fibrosis transmembrane conductance regulator, or CFTR (Wilke et al. 2007). Epithelial sodium channels located on eccrine gland membranes also perform the task of reabsorbing sodium ions that are secreted in sweat (Stutts et al. 1997). A deficient epithelial sodium channel, such as in the case of cystic fibrosis, results in salty sweat because the sodium ions are not reabsorbed into the body and remain in the sweat (Di Sant'Agnese et al. 1953). While sweat contains urea, its small concentration suggests that the role of sweat is primarily to regulate body temperature and not to excrete harmful substances from the body (Huang et al. 2002).

There are two main types of sweat glands: eccrine and apocrine sweat glands. Eccrine glands are found throughout the body, especially on the palms and soles of the feet, and help secrete excess water from the body. Eccrine sweat glands play a central role in ► [thermoregulation](#) and are vital to life and are functional from birth. All the sweat glands in the human body together would resemble the size of a kidney. Humans can perspire, or sweat, nearly 10 liters a day (Wilke et al. 2007; Sato 1977). Sweat gland activity is controlled by the central ► [nervous system](#) and the ► [hypothalamus](#) (Wilke et al.

2007). Eccrine sweat contains sodium, chloride, potassium, calcium, lactate, ammonia, amino acids, urea, bicarbonate, as well as proteins (Wilke et al. 2007).

The scent of sweat comes from bacterial activity on apocrine sweat gland excretion. Apocrine sweat glands are larger than eccrine glands and are commonly found in the armpit and between the anus and genitals, and other hairy sites on the body. This is because they secrete into the hair canal rather than onto the skin itself. They do not play a role in the excretory system and only begin functioning during ► [puberty](#) due to hormonal changes (Wilke et al. 2007). The secretions of apocrine glands contain nutrients for bacteria on the skin, and when the sweat decomposes it creates an odor. A third type of sweat gland is the apoeccrine gland, which is a mixed gland that is thought to also be found in hairy areas. They are believed to develop from eccrine glands once an individual hits puberty, since the proportion of eccrine glands decreases as people get older. Due to their origins, they also secrete sweat with a similar composition when it comes to concentrations of molecules like sodium and potassium to that of the eccrine glands. Apoeccrine glands have higher overall sweat rates and so are believed to contribute heavily to sweating in areas like the armpits (Wilke et al. 2007).

## Summary

The excretory system consists of several organs that aide in the removal, secretion, or elimination of metabolic waste products and other harmful substances that are created in the body as a means of achieving homeostasis. The kidneys and their nephrons filter blood using a semipermeable membrane as it makes its way through the body as a part of the circulatory system. The filtrate that is produced travels through the urinary system and is expelled from the body out the urethra during a process known as urination. Kidney stones served as an example of the dangers of what occurs when material that should be dissolved into the urine is not. The liver performs a variety of functions, including the production of

bile and the creation of urea or uric acid. Urea is a major component of urine. The large intestine is a part of the digestive system and gastrointestinal tract that is responsible for extracting water from solid waste matter passing through from the small intestines. This waste matter exits the body as feces or stool out of the rectum or anal canal during defecation. When waste matter is not released or released too early, these are signs of constipation as the stool hardens too much or even diarrhea as excess water is not removed properly. Finally, the skin and sweat glands help to release hazardous elements such as urea. However, the minute levels detected of these suggest that the larger role of sweat and perspiration is thermoregulation.

## Introduction

Executive function (EF) is a heterogeneous construct widely used to refer to a conspicuous number of higher-order cognitive processes devoted to the monitoring and control of thoughts and actions. EF is generally regarded as being particularly important in novel or unfamiliar situations in which thoughtful and cautious behavior, instead of automatic and impulsive response, is required (Diamond 2013). The functioning of executive processes is thought to rely on the prefrontal cortex (PFC) in both humans and non-human animals, regardless of the anatomical variations existing across different species (Robbins 2000).

Despite the fact that EF is still often mentioned as a unitary system, there is growing consensus that regards it as a multidimensional construct including separable components. A possible clarification on the architecture of EF comes from factor analyses conducted on human populations (school-aged children, adolescents, and adults), which have identified three core components (Miyake et al. 2000). First, inhibitory control, defined as the ability to suppress a prepotent

response in order to achieve a relevant goal. Importantly, individuals can exert inhibition by not only suppressing an impulsive response, but also initiating a subdominant (conflicting) action at one time. Second, working memory, which refers to the cognitive processes designated to hold information in mind in order to recall and work with it at some point in the future. Third, cognitive flexibility, which facilitates adjustment to changes and perspective shifting to solve a problem. Evidence from neuroimaging studies gives further support to the non-unitary organization of EF, showing that different areas of the PFC subserve different EF components in both humans and nonhuman animals. However, a clear distinction between EF components is pretty challenging in experimental practice, since a task that is supposed to purely examine a given EF component is concurrently likely to elicit other nonrelevant cognitive processes.

In humans, EF and its neural correlates were discovered in brain-injured patients in the nineteenth century. Later on, research focused on war veterans with brain injuries and on patients affected by neuropsychiatric disorders such as attention-deficit/hyperactivity disorder (ADHD), obsessive compulsive disorder, and schizophrenia. Poor EF is associated with overeating, substance abuse, and social problems, whereas good EF predicts success in school and overall quality of life. Over the past two decades, EF has been the object of notable comparative studies, which have mainly involved nonhuman primates and rodents. In particular, behavioral and neurobiological investigations in animal models allowed us to comprehend the relative contribution of the different areas of the PFC to the diverse EF components. In the ensuing sections, a brief overview of the most up-to-date literature on EF in human and animal populations is presented, with a special focus on comparative approaches.

## Inhibitory Control

In humans, inhibitory control is considered a highly adaptive ability, as it involves voluntary control over some of the most important processes for an individual's social adjustment, such as

internal states (e.g., intentions, emotions, and beliefs) and behavior. This ability emerges early in development and starts to become evident and measurable in the first years of life. However, inhibitory control is subject to noticeable improvements during the preschool period, between 3 and 6 years of age, and becomes more specialized throughout adolescence. The preschool age is a crucial period for the development of inhibitory control as, if children are more able to exert self-control at this age, they are more competent in social situations, less prone to risky behavior, and more likely to show better academic performance later in life. In comparative research, human beings show better inhibitory control than nonhuman animals and, among the latter, considerable interspecific differences, which are likely related to their feeding ecology, have been reported (MacLean et al. 2014). Two classes of tasks are generally used to assess inhibitory control: conflict and delayed gratification tasks. In conflict tasks, individuals are required to suppress a dominant response and to concurrently provide a subdominant response. In delayed gratification tasks, individuals are required to wait in order to obtain something pleasant in the future.

Examples of conflict tasks are the A-not-B task, the detour-reaching task, and the reverse-reward contingency task. In the A-not-B task, the subject repeatedly observes the experimenter hiding an object at location A; then, after a few trials, the experimenter hides the object at location B. Incorrect attempts of retrieving the object by searching at location A denote prepotent motor responses. Children begin to succeed in this task by 10–12 months of age (Diamond 2013). Among nonhuman primates, considerable interspecific differences have been observed, with apes showing a better performance than several monkey and lemur species (MacLean et al. 2014). In the detour-reaching task (or object-retrieval task, Diamond 2013), the subject has to inhibit from reaching directly for a visible reward, which is placed behind a clear barrier or inside a transparent container with open ends. To obtain the reward, the subject must detour around the barrier and reach from the side. Very young infants show a prepotent tendency to reach directly for the visible reward, and they begin to succeed around

their first birthday. As with the A-not-B task, in the detour-reaching task children and apes show a better performance than several monkey and lemur species (MacLean et al. 2014). Importantly, in all species tested so far, a better performance is achieved when the barrier blocking the reward is opaque rather than transparent. In the reverse-reward contingency task, the subject is faced with a series of choices between different quantities or types of reward and has to select the smaller/less preferred option to receive the larger/more preferred one, thus inhibiting the spontaneous tendency to reach toward the larger/more preferred reward. All the populations tested so far (preschool children, lemurs, monkeys, and apes) were more successful when appetitive rewards were replaced by symbolic stimuli, which decrease the attractiveness of the options and the consequent impulsive responses toward them.

Delayed gratification tasks include delay choice and delay maintenance tasks. In delay choice tasks, the subject is presented with a series of choices between a small/less preferred reward, immediately available, and a larger/more preferred reward, available after some delay. Individuals often prefer the immediate option, demonstrating a devaluation of future outcomes: a process known as delay (or temporal) discounting. In delay maintenance tasks, after an initial choice to delay gratification, the subject is required to actively maintain the decision to wait for the large/more preferred reward throughout the delay, since the immediate, small/less preferred option remains continuously available. Importantly, the few studies that have tested the same subjects in delay choice and delay maintenance tasks (within human, nonhuman primate, and rodent samples) have found modest or scarce correlation between performances, as these tasks tapped different components of inhibitory control (Addessi et al. 2013).

## Working Memory

In 1974, Baddeley and Hitch proposed a theoretical model of working memory, which includes the ability to retain information no longer present in the environment into short-term storage and to

mentally manipulate a limited number of items during complex cognitive tasks. Working memory consists of three components: (i) the central executive, which provides processes of attention and control of information, (ii) the phonological loop, specialized in verbal information processing, and (iii) the visuospatial sketchpad, specialized in nonverbal information processing. Since then, working memory has been theorized in increasingly sophisticated forms, underlining its central role in important cognitive processes, such as language, reasoning, problem solving, and academic success (Towse and Cowan 2005). Baddeley (2000), for instance, has proposed a fourth component of working memory, the episodic buffer, which provides temporary storage of information held in a multimodal code.

Human infants, beginning from 9 to 12 months of age, can hold few items in mind. Then, working memory develops gradually over childhood and adolescence, probably due to an enhancement in the speed of information processing and in the capacity to inhibit interferences, and considerably declines in older adults, likely due to the higher vulnerability to interferences and to a decreased inhibitory control (Diamond 2013).

In humans, working memory is often assessed through the dual-task paradigm, which requires individuals to complete a memory span task and a processing task at the same time. In nonhuman animals, working memory is evaluated by means of tasks that require the subject to choose a reward location after a delay. The spatial delayed response task is used to investigate working memory in both humans and nonhuman primates. In this task, the subject observes the experimenter baiting one of two (or more) locations. Then, all locations are covered with identical objects, and a barrier is placed between the subject and the food locations. After a delay, the barrier is raised and the subject is allowed to choose the baited food location. As in humans, also non-human primate individuals are less accurate as delay increases; moreover, performance critically depends on dorsolateral PFC functioning and declines with age. The delayed alternation task is used to assess working memory in rodents by means of a T- or Y-maze apparatus. On the first trial, rats are

rewarded for entering either of the choice arms. From the second trial on, rats are only rewarded if they enter the arm which was not chosen on the previous trial and working memory is assessed by varying the delay between successive trials.

## Cognitive Flexibility

Cognitive flexibility, also known as set shifting or mental set shifting, involves the capacity to rapidly switch between different perspectives and implement novel strategies to cope with adverse situations or changed circumstances. In humans, cognitive flexibility emerges later and improves more slowly than the other EF components; as working memory, it also declines with age (Diamond 2013).

In most tasks used to assess cognitive flexibility, participants are required to switch from one mental set to another, according to the feedback provided by the experimenter. A classical task used to investigate cognitive flexibility is the Wisconsin card sorting task. This task requires the subject to sort a deck of cards according to a certain feature (color, shape, or number), which is learnt by trial and error through the feedback provided by the experimenter. Then, during the experiment, the sorting criterion changes without notice, and the participant is required to infer the new sorting criterion on the basis of the experimenter's feedback and to flexibly switch to sort cards according to the new perceptual feature. Performance in this task depends on dorsolateral and orbital PFC functioning (Dias et al. 1996). Attentional set-shifting tasks can be used to compare cognitive flexibility between humans and nonhuman species. In these tasks, an extra-dimensional shift occurs when the participant is initially trained to respond to one of the two dimensions of a stimulus composed of two dimensions and is subsequently required to respond to the alternative stimulus dimension. In contrast, an intra-dimensional shift occurs when the participant is required to respond to different stimuli characterized by the same dimension. Extra-dimensional shifting takes significantly longer to be learnt than intra-dimensional shifting

(Chudasama 2011). Three-year-old children can pass tests where they need to invert a rule while the features of the stimuli remain unvaried (*response shifting*). In contrast, they encounter difficulties when perceptual aspects of the stimuli change (*attention shifting*). Such distinction is well supported by neuroimaging studies indicating that, in both humans (children and adults) and nonhuman animals, response and attention shifting are linked to different areas of the brain, with the first being connected with the medial frontal areas and the second involving the lateral frontal areas (Garon et al. 2008). In a particular version of the attentional set-shifting task adapted for rodents, individuals are required to discriminate between stimuli that differ on odor and texture in order to retrieve the reward (Birrell and Brown 2000). The reversal learning task is also widely used to evaluate cognitive flexibility in humans and nonhuman animals (Chudasama 2011). In this task, the subject initially learns that the response to one of two stimuli is consistently rewarded. Then, the stimulus-reward contingency is reversed, and the subject must flexibly switch to select the alternative option in order to be rewarded. Performance in this task is highly sensitive to orbital PFC lesions and to serotonin depletion, but not to dopamine depletion.

## Executive Monkey Study

Jay M. Weiss

Emory University, School of Medicine, Atlanta, GA, USA

## Historical Development of “Psychosomatic Medicine”

The “executive monkey” study, which was published over 60 years ago in 1958, remains in all probability the most well-known experiment in a field referred to as Psychosomatic Medicine. Given its prominence in this field, we will therefore consider the definition and historical development of the concept of Psychosomatic Medicine before describing the details of the “executive monkey” experiment and its findings. That mental or psychological events could

influence disease was known as far back as the early Greeks, as Hippocrates and Galen proposed that mind and body were inseparably linked and that physical wellbeing was tied to psychological wellbeing (e.g., Coxe 1846). Similar sentiments were expressed during the centuries that followed, so that by the eighteenth and nineteenth centuries one finds definitive pronouncements that psychological factors profoundly influence disease. For instance, Daniel Hack Tuke, the prominent British physician and psychiatrist, published a volume in 1872 titled “Illustrations of the Influence of the Mind Upon the Body in Health and Disease” (Tuke 1872) in which he described thought processes and emotions both causing/exacerbating disease as well as ameliorating it (for a detailed quotation from Tuke in this regard, see introductory section Weiss 1972). The relationship between psychological processes and bodily function (symptoms and disease) soon received new attention with the studies and writings of Sigmund Freud at the end of the nineteenth century when he hypothesized that psychic conflicts could find expression as physical disabilities in hysteria (Freud, 1890–1893; translated by Strachey, 1955).

The early to mid-twentieth century saw a renaissance of interest in what came to be known as psychosomatic medicine – the relationship of psychological events to somatic disease. An excellent recounting of this history can be found in an article by Lipowski (1984). He finds the term “psychosomatic medicine” to have been first used in 1922. Important events thereafter were the publication in 1935 of Helen Flanders Dunbar’s book titled, “Emotions and Bodily Changes: A Survey of Literature on Psychosomatic Interrelationships” (Dunbar 1935), followed by the founding of the Journal “Psychosomatic Medicine” in 1939. Psychoanalytic analysis introduced by Freud reached perhaps its highest development in relation to somatic disease in the work and writings of Franz Alexander, who saw a variety of different diseases as resulting from specific intrapsychic conflicts (Alexander 1950). In the case of peptic ulcer, Alexander posited that this pathology resulted from the ulcer patient’s unconscious desire to be dependent and taken care of while at the same time adhering to the compulsion

to act independently and assertively, with the unconscious desire resulting in the need to be constantly fed causing chronic hypersecretion of stomach acid and eventual ulceration. Needless to say, it is difficult, if not impossible, to see how this intrapsychic conflict could explain the duodenal ulcers that were found in the “executive” monkeys, and as the result of challenges such as this as well as other psychoanalytic explanations were soon viewed as conjectural and unlikely to be correct. Meanwhile, controversy raged within Psychosomatic Medicine as to whether mental events could actually cause disease (called “psychogenesis”) or whether mind and body were really inseparable and that disease resulted from physiological processes necessarily involving interplay of psychological and somatic factors. While the field has settled on the latter view (as evidenced in the Lipowski article), even at the present time the term “psychosomatic” is commonly used to mean that psychological influences lead to disease. For example, in 2016, author Claudia Kalb described Charles Darwin’s continuing gastrointestinal problems, asking whether these problems might have been caused by an infectious tropical bug picked up in his travels aboard the ship *Beagle* or “were Darwin’s lifelong symptoms psychosomatic – physical manifestations of ongoing mental stress?” (Kalb 2016).

### **The “Executive Monkey” Experiment: Description and Findings**

Turning now to the “executive monkey” experiment, this experiment utilized pairs of rhesus monkeys, ultimately four pairs of monkeys. The two monkeys of each pair were restrained in chairs as shown in Fig. 1. The monkeys were subjected to intermittent electric shocks that one member of each pair, shown at the left side of the figure, could control by pressing a lever in front of it which postponed occurrence of the next shock, so that shock only occurred when this monkey, dubbed the “executive monkey,” failed to activate its lever. The second member of the pair also had a lever mounted at the front of its chair but the lever was inactivated so that this monkey received the

E

**Executive Monkey Study, Fig. 1** A pair of rhesus monkeys in chairs as used in the “executive monkey” study. The monkey on the left is controlling (avoiding) delivery of shock to its feet by pressing the lever mounted at the front of its chair, while the monkey on the right (yoked

monkey) receives the same shocks as the avoidance, or “executive,” monkey at the right. The yoked monkey also has a lever mounted at the front of its chair, but this lever is inactive and the yoked monkey is not attending to it. As shown in Brady (1958) Scientific American article

same shocks as did the “executive” but did not have any control over shock occurrence. Thus, one monkey of the pair exerted control over the occurrence of shock while the other monkey, called the “yoked” monkey, had no control, with both monkeys receiving the same shocks throughout the experiment.

This experiment attracted so much attention because, when the monkeys were maintained in these experimental conditions for many days, the “executive” monkeys eventually died apparently as a result of gastrointestinal pathology including lesions and perforating ulceration, while the “yoked” monkeys developed no such pathology and lived on. It thus appeared that being the “executive” and exerting control caused pathology and death, whereas not exerting control avoided this detrimental outcome.

The history of how the experiment unfolded is important for understanding and interpreting the results. The first report of the procedure described above appeared in the Journal “Psychosomatic Medicine” in 1958 in an article for which R.W. Porter was the first author (Porter et al. 1958). Titled “Some Experimental Observations on Gastrointestinal Lesions in Behaviorally Conditioned Monkeys,” the article describes that in various behavioral studies being undertaken with rhesus monkeys at Walter Reed Army Medical Center in Washington, DC, gastrointestinal pathology leading to death began to show up in many of the animals. The procedures performed on monkeys confined in chairs as shown in Fig. 1 involved conditioned anxiety (shock paired with a signal) and punishment (shock given for performing a response otherwise rewarded with

a sugar pellet), as well as a combination of such procedures. Eleven of nineteen animals undergoing such procedures died during the experiments, and on autopsy gastrointestinal pathology was discovered as the likely cause of death.

The paper by Porter et al. concludes with a description of the first two pairs of monkeys that eventually constituted the “executive” monkey study. In an attempt to determine that behavioral conditions led to the pathology seen in the 11 monkeys described above – which the investigators strongly believed to be the case – and perhaps gain insight into what conditions could do this, two monkeys were subjected to a shock avoidance paradigm, this being the lever press contingency whereby these two animals were made to avoid/control shock by pressing the lever at the front of their chair. The avoidance procedure, however, leads to animals receiving electric shocks, so that any pathology eventually observed could be simply a result of the physical stressor of electric shock being given to the monkeys and not because of the behavioral condition of performing an avoidance response. In order to rule out the possibility that electric shocks alone might produce the pathology eventually seen, this aspect of the experiment included a “yoked” animal for each avoidance monkey, these yoked animals having no control over shock and not engaging in avoidance responding but receiving the same shocks as the monkeys performing the avoidance response. If these yoked animals did not develop pathology, it would be evident that the electric shock itself did not cause such pathology. It is of note, therefore, that the “executive” monkey experiment was not designed to determine the effects of having control versus not having control in a stressful situation, as subsequent scientific and popular perception seized upon, but included yoked animals (i.e., animals having no control) to rule out electric shock as the cause of pathology. That the yoked animal was included in the study to exclude electric shock as being responsible for development of pathology is explicitly stated in the subsequent summary article that appeared in *Scientific American* (Brady 1958).

A second important paper appeared later that year in which findings from “executive”-yoked pairs reached  $n = 4$  (eight monkeys); similar

results were seen with the addition of two pairs of monkeys as reported in the first paper described above. Thus, in the total of four pairs, which constituted all of the animals eventually reported for the “executive monkey” study, all four “executive” monkeys died of gastrointestinal pathology whereas the four yoked animals showed no behavioral impairment, and, when sacrificed, showed no G.I. pathology (Brady et al. 1958). Following this, the most famous article describing these results – “Ulcers in ‘Executive’ Monkeys” – appeared in *Scientific American* and presented the data from the four pairs of monkeys (Brady 1958).

That receipt of electric shock was not the cause of the pathology seen in these monkeys becomes even more evident when the schedule for delivery of shock and the avoidance behavior it generated is examined (Brady et al. 1958; Porter et al. 1958). The avoidance schedule to which the “executive” monkeys were subjected is called a “Sidman avoidance schedule” named after its developer, Dr. Murray Sidman. In this schedule, shocks were not preceded by any warning signal, and brief shocks (5.0 mA intensity, 0.5 s in duration) were given every 5.0 s (shock delivered to the feet of the animals) unless the active lever is pressed in which case the next shock was delayed for 20 s. Thus, unsignaled shocks occurred in a train of one brief shock every 5.0 s unless an avoidance response was made which then delayed the onset of the next train of shocks for 20 s. When this schedule was in place, “executive” monkeys (i.e., avoidance monkeys) proved remarkably proficient at acquiring and practicing the lever press response to avoid (i.e., postpone) shock. The investigators report that within a few hours of the beginning of training, stable avoidance responding emerged, the avoidance monkey making approximately 15–30 responses per minute. This response rate remained essentially unchanged during the entire experiment. As a result, shocks received by the monkeys never exceeded 2 per hour and typically averaged less than 1 per hour. Thus, very few shocks were received by the monkeys throughout the course of the experiment; shocks occurred so infrequently it is not surprising that the results revealed (by inspection of yoked animals) that this physical

stressor did not generate gastrointestinal pathology.

Describing the course of the experiment and the development of pathology, the animals were confined in the chairs as shown in Fig. 1 continuously. Each day of the study was divided into “time-in” periods lasting 6 h during which shocks would occur (and the executive [avoidance] monkey therefore was going to respond to control shock and the yoked monkey also received shock if the avoidance monkey did not avoid shock) and “time-out” periods also lasting 6 h when no shocks would occur. These periods alternated, so that a 24-h day consisted of two 6-h “time-in” periods and two 6-h “time-out” periods. The presence of the “time-in” phase was signaled by illumination of a red light in full view of both animals of the pair. Regarding development of gastrointestinal pathology and death of the “executive” animals, one died after 9 days of this procedure while the other three died after 23, 25, and 48 days. Pathology found in the “executive” monkeys was gastric hemorrhage and erosions as well as duodenal ulcers that perforated in two instances. When the yoked monkeys were sacrificed shortly after the death of their matched “executive” partners, yoked monkeys showed no evidence of any gastric pathology.

In the *Scientific American* article by Brady (1958), a brief description is given of other testing conditions (described as being “still in progress”), such as prevention of social interaction between the two monkeys and exposure to different time-in, time-out intervals for responding. However, the details of these studies were not given nor, more importantly, were these procedures and their outcome described in any subsequent formal publication, so the number of monkeys that comprised the “executive monkey” study remains four pairs of animals.

### **Subsequent Research: Being Able to Control Found to Reduce Stress and Pathology**

Popular press and scientific researchers quickly realized that the “executive” monkey study compared animals that had control over a stressor (i.e.,

monkeys able to perform the avoidance response) with yoked animals that did not have any such control, and so the effects observed were viewed as the consequences of exerting control versus not having that ability, or, as the results suggested, that responsibility/burden. The study was thenceforth seen in this light, despite the fact that, as explained above, the investigators who carried out the experiment did not intend to study effects of having control versus no control but, instead, included yoked monkeys to set up what is called a “control condition” to rule out the possibility that shock alone produced pathology. Regardless, the “executive monkey” study was thereafter seen as demonstrating the effect of having control versus no control.

While the pathological findings of the “executive monkey” study seemed plausible given the amount of responding by the avoidance monkeys versus the nonresponding of the “yoked” monkeys, other data looking at the consequences of having control versus noncontrol, though extremely limited in amount and scope, did not point to the same conclusion. In 1948, O. Hobart Mowrer and his student P. Viek had found that rats able to control (terminate) an electric shock by jumping into the air showed less subsequent fear (i.e., were more willing to approach and eat food) than were rats that received equal shocks but could not terminate them (Mowrer and Viek 1948). Though it was obvious that the conditions of the “executive monkey” study and the experiment by Mowrer and Viek were very different, the contrasting findings suggested that the consequences of having control versus no control might not be described comprehensively by what was seen in the “executive monkey” study. Following publication of the “executive monkey” findings, however, no additional experimental results looking at consequences of having control versus no control appeared for approximately 10 years, but then new findings were reported at this time.

In 1968, 10 years after publication of the “executive monkey” study, the findings of my Ph.D. dissertation research were published in which rats were the subjects (Weiss 1968). These data also pointed to a conclusion opposite to that suggested by the “executive” monkey study,

indicating that control over a stressful event lessened consequences of stress and stress-induced pathology. This study examined effects of having control versus no control over electric shocks on (a) body weight and food/water intake, (b) fearfulness as measured by willingness of the rats, when thirsty, to drink in the control versus no control environment, and (c) development of gastric pathology (gastric erosions). Using matched triplets of rats in which one rat could avoid and escape electric shocks (i.e., control occurrence and duration of any shocks received), a “yoked” animal that received the same shocks but had no control over them, and a nonshock subject that simply remained in the apparatus and received all stimuli as the other two animals but did not receive any shocks, differences between these three types of animals were observed. The experimental design for a triplet is shown in Fig. 2,

although the particular apparatus shown in this figure was used in a later experiment and differs somewhat from the apparatus employed in Weiss (1968) (apparatus used in Weiss 1968 is shown in that article).

A highly important detail in these studies, which can be seen in Fig. 2, was that electric shocks received by the rats were delivered through electrodes affixed to the rat’s tail, a procedure prompted by the insight of my brilliant Ph. D. advisor, Professor Neal E. Miller. (Neal Miller was a member of the National Academy of Sciences and first recipient of the National Medal of Science in the field of Social and Behavioral Science [1964], receiving this award in the third year after the Medal was established by President John F. Kennedy.) Miller had criticized the original Mowrer and Viek experiment on the basis that the animals were given shocks via a grid floor.

**Executive Monkey Study, Fig. 2** The experimental design paradigm for matched triplets of animals as used in Weiss (1968) and Weiss (1971a, b, c). The Avoidance-escape animal shown at left could control shock by performing a response (wheel-turn shown in this figure); this is noted as connection of wheel “To shock control.” Both the Avoidance-escape and the Yoked animal shown at center which is unable to perform a response to affect shock received exactly the same shocks via tail electrodes, with their tail electrodes wired in series into the same

electrical circuit; electrode connection is noted as “To shock source.” The third animal shown at right (“No shock”) receives all stimuli throughout the procedure as the other two animals of the triplet except that it receives no shocks as its tail electrodes are not connected (“No connection”). Apparatus shown here was used in Weiss (1971a, b, c), while apparatus and responses to control shock were different in Weiss (1968) (see text), but all aspects of triplet design shown here were the same in all of these experiments

Miller pointed out that on a grid floor, rats can change their bodily posture to lessen shock and/or jump completely off the floor to momentarily avoid shock, so that using this method to deliver shock cannot insure that the two matched animals (i.e., avoidance-escape animal and yoked animal) will get exactly the same shocks. Consequently, differences seen between these conditions might be due to the animals learning different postural maneuvers to consistently receive different amounts of shock. When I originally proposed to Miller to study control versus noncontrol for my dissertation research, he called attention to this problem and urged me to try to develop shock electrodes that could be affixed to the animal's body to eliminate the ability of the rat to make postural changes that would alter shock. Fortunately, I was able to accomplish this during the next few months, and the method used has been published (Weiss 1967). Consequently, all experiments using the triplets as described and shown above employed tail electrodes affixed to the rats for delivery of shocks. With each matched pair of avoidance-escape and yoked animals having their shock electrodes wired in series into the electrical circuit for all of the experiments, shocks received by these two animals were necessarily exactly the same in number, duration, and intensity.

The results reported in Weiss (1968) were briefly described as follows: in the first experiment, animals were exposed to avoidance-escape versus yoked conditions for a session lasting 2.5–3.0 h (i.e., avoidance-escape rats could avoid tail shock or terminate it by jumping onto a shelf while yoked animals received the same shocks but could not control them). Twenty-four hours later, avoidance-escape rats were found to be significantly heavier in body weight than the yoked animals, having eaten more food during the night after the stress session than did yoked animals. Yoked animals also weighed less than matched no-shock animals, while avoidance-escape animals were only slightly lighter than the no-shock subjects. In the second part of this study, all rats were made thirsty by water deprivation and placed into the shock environment where a water tube was now present. Yoked animals were considerably more reluctant to approach

the drinking tube than were avoidance-escape or nonshock subjects, thereby showing that yoked rats, as a result of exposure to shocks over which they had no control, were now more fearful in that environment than the other two groups. Finally, to assess gastric pathology as was measured in the “executive monkey” study, a second experimental situation was used in which animals were mildly restrained in a tube wherein avoidance-escape rats could control shock to its tail by a nose-poke at the front of its tube, “yoked” rats could nose-poke but without effect on shocks and received equal tail shock as their matched avoidance-escape partners, and no-shock rats did not receive shocks in this condition. When gastric pathology was assessed after rats had been in these conditions for 48 h, “yoked” rats developed clearly more gastric erosions than were seen in the other two groups.

Thus, the first foray into examining effects of control versus noncontrol on various physiological indices after appearance of the “executive monkey” study yielded results consistently opposite to its findings, including what was observed when development of gastric pathology was assessed. However, it was the next series of experiments that led to the most illuminating results; these findings will now be described.

### **Addressing the “Executive Monkey” Findings: Assessing the Importance of Signals Before Shock**

The next experiments attempted to determine why the findings in Weiss (1968) differed from what was seen in the “executive monkey” study. As described earlier, the “executive monkey” procedure required the animals controlling shock to respond in a “Sidman” avoidance procedure in which all shocks occurred without any signal preceding them; responses simply postponed a train of shocks before which no warning signal had occurred. In contrast to this, in Weiss (1968), shocks had always been preceded by a warning signal. In those experiments, therefore, a warning signal informed the rats that shock onset was imminent, and also responses made during the

warning signal not only avoided shock (i.e., caused shock not to occur) but terminated the warning signal to convey additional external information for the animal exercising control. Was a key factor in producing the difference the presence of a warning signal before shock as used by Weiss versus simply postponing shocks that had no warning signal preceding them as was the case in the “executive monkey” study?

To test this, the importance of warning signals was examined (Weiss 1971a). In this large study, rats were exposed to electric shocks that were (1) unsignaled, or (2) preceded by a warning signal (“beeping” tone auditory signal beginning 20 s before shock), or, additionally, (3) preceded by a series of auditory warning signals (different tones) even more elaborate than a usual single warning signal (i.e., the “beeping” tone). As previously, matched triplets of rats were used; the design as well as the apparatus for this study is shown in Fig. 2, and an animal in an enclosure with the wheel mounted at the front is shown in Fig. 3. In all three warning-signal conditions, a response by the avoidance-escape rat – turning of the wheel at the front of its apparatus – postponed the onset of shock, which consisted of a train of brief, rapidly-occurring shock pulses, for 200 s (i.e., this was an avoidance response). If the shock train had begun, the response immediately terminated shock and shock did not occur again for 200 s (i.e., this was an escape response). Thus, the avoidance-escape rat exerted control over shock, avoiding/postponing shock or terminating shock if it had begun, and the effect of a response by this animal on shock – postponement of the next shock for 200 s – was exactly same in the three warning-signal conditions.

What therefore differed in the three warning-signal conditions was (a) how much external information rats got as to when shock would occur, and (b) how much external information rats got when the avoidance-escape rat responded. In the unsignaled shock condition, these rats, like the “executive monkeys,” got no external feedback informing them when shock would occur, and also they did not experience any stimulus change in their environment when they made an avoidance response postponing shock. For these

**Executive Monkey Study, Fig. 3** The Plexiglas enclosure used in Weiss (1971a) and also Weiss (1971b, c). Each rat was placed in this Plexiglas chamber where it was able to turn the wheel mounted at the front of the enclosure. Electric shock could be delivered to the rat’s tail protruding through the rear end of the enclosure via electrodes attached to the tail. Each of these enclosures was placed into a separate soundproof chamber so that each animal was isolated and separated from other two animals of its triplet. The white tubing leading from the top of the wheel-turning enclosure is an air exhaust that provided constant ventilation of the enclosure. The graduated cylinder seen at the rear contains water; a spout from the cylinder protruded into the enclosure through a small hole thereby providing the rat access to drinking water throughout the procedure

animals, only an escape response produced any external change because in this case the shock train terminated. For signaled shock animals, rats knew when shock was imminent (i.e., the “beeping” tone warning signal sounded), and if the avoidance-escape animal responded during this warning signal (avoidance response), an external stimulus change occurred because the warning signal immediately terminated. For the third warning-signal condition, even more information was provided; this condition essentially provided an external clock leading up to shock. In this condition, called Progressive signal, a succession of warning signals was initiated 30 s after a shock had occurred, and consisted of five tones that became higher in frequency pitch and louder every 30 s until the “beeping” tone warning signal then began 20 s before shock. Note that the yoked

and nonshock animals of each triplet heard exactly the same external tone signals as the avoidance-escape animal, and yoked animals experienced the same shocks and shock terminations as well. Animals were exposed to these conditions for 48 h, at which time they were sacrificed and the presence of gastric pathology (gastric erosions) was determined and quantified.

### **Findings from This Analysis: Exerting Control Reduces Stress and Ulceration in All Signal Conditions. Subsequent Analysis Leads to a Promising General Formulation**

The results of this study did not indicate that the simple presence or absence of warning signals was the key to understanding the “executive monkey” findings. In all three conditions – Unsignaled shock, Signaled shock, and the more elaborate warning signal condition called Progressive signal – the avoidance-escape rats able to exert control over shock developed less pathology and evidence of stress than did their matched yoked animals that could not control shock (Weiss 1971a). Differences in gastric ulceration between avoidance-escape and yoked rats were statistically significant in all three signal conditions, favoring avoidance-escape animals over yoked animals. On its face, therefore, the “executive monkey” study appeared to be an anomaly, and writings between 1958 and the beginning of the 1970s that emphasized the negatives of having the burden of being in control were left lacking empirical support.

However, detailed analysis of the large amount of data generated by this study (20 matched triplets were included in each signal condition) led to a theoretical formulation that to this day appears to be valid and subsequently led to a potential explanation for the “executive monkey” findings. Examining the wheel-turning behavior of the rats, particularly the animals in the unsignaled shock condition, revealed that rats which made the most responses tended to develop the most severe gastric ulceration. **This led to the first leg of the hypothesis: As coping attempts (i.e., responses)**

**by the animal increases, stress and pathology tends to increase.** However, this relationship between the amount of responding and development of pathology was observed to be much weaker in avoidance-escape animals of the Signaled shock condition, and, in particular, was weakest in avoidance-escape rats of the Progressive signal condition. Why? The idea emerged that the response rate of animals could be high but if the amount of information they received about the success of their responses was also high, pathology would be prevented from developing. What was the relevant information? In a stress situation, the relevant information that the animal wants is that the danger/stress situation is over, it has ended, it has gone away. In other words, it seeks stimuli not associated with danger/stress/electric shock; i.e., it wants a stimulus condition that represents safety. When shock is signaled, and even more so in the Progressive signal condition, wheel-turning responses by the avoidance-escape animal often terminate warning signals to immediately bring about silence which is a safety period insofar as silence for these animals is present when shock is not occurring or imminent. Consequently, warning signal terminations produce a large amount of relevant information that the animal seeks. This “good information” from a response was called “relevant feedback.” **This led to the second leg of the hypothesis: As relevant feedback from coping attempts (i.e., responses) increases, stress and pathology tends to decrease.**

Thus the consequences of being in a stressful situation are a function of two factors: adverse effects increase as the number of coping attempts (responses) increases, but then these adverse effects are held in check by the outcome of the coping attempts, decreasing (or failing to increase) as the relevant feedback resulting from coping attempts (responses) increases. The combination of these two functions has been presented graphically, which is shown in Fig. 4 (from Weiss 1971a). This figure shows the prediction of adverse effects generated by the convergence of the two functions (adverse effects in this case labeled “ulceration” insofar as this is what was measured in the experiment described above). The

**Executive Monkey Study, Fig. 4** The three-dimensional plane describing the proposed relationship between the two independent variables – “Responses” (coping attempts) and “Relevant Feedback” from such coping attempts – and how this is related to the severity of stress and/or pathology (labeled here “Ulceration”). As Responses increase and Relevant Feedback decreases, stress/pathology increases. For ease of reading, the axes for Responses and Relevant Feedback are labeled in the foreground; customarily, these labels are placed on these axes in the background. Also presented in this figure is a hypothetical example showing the amount of pathology resulting from (A) a low number of responses being made (B) when these responses generate a low amount of relevant feedback

figure includes a hypothetical example indicating how much pathology will occur when a certain number of responses are made in a given situation and these responses produce a certain amount of relevant feedback.

Figure 5 shows how the results of exposure to the three different warning signal conditions in Weiss (1971a) conformed to the formulation shown in Fig. 4. Wheel-turn responses were counted, so this was known for all groups. Regarding relevant feedback, this could be estimated as well. For the avoidance-escape groups, those in the Signal condition received a moderate amount of

**Executive Monkey Study, Fig. 5** Results found in Weiss (1971a) for the Avoidance (Avoidance-escape) and Yoked groups of the three different signal conditions. For each group, the amount of gastric ulceration observed (height of bar) is shown at the point where the amount of responding observed in that group and the amount of relevant feedback from responding in that condition intersect. Note that for Yoked groups, amount of relevant feedback in all conditions is zero, which is necessarily the case when animals have no control over the stressor

relevant feedback for responding, resulting from signal terminations and escape responses, whereas those in the Progressive signal condition received even more relevant feedback because of the presence of more auditory signals that responses terminated. The lowest amount of relevant feedback was experienced in the unsignaled (No Signal) condition. Here avoidance responses postponed shock but changed nothing in the external environment; only escape responses (shock terminations) produced relevant feedback in this condition. These three conditions are represented appropriately in Fig. 5. The most interesting and informative groups, however, are the yoked groups. *This formulation tells us why it is so detrimental to have no control over a stressor. For these animals, relevant feedback from any response is always zero – all responses have no effect on the environment or the*

*stressor*. That is, in fact, what it means to be without control – relevant feedback from any coping attempt is zero. In this condition, adverse effects of stress are a direct function of the number of coping attempts made – the higher the response rate in this condition, the more the pathology. This relationship can be seen in the three yoked groups shown in Fig. 5.

### Tests of the Formulation and Explaining the “Executive Monkey” Findings

The validity of the formulation presented in Fig. 4 was then tested in two experiments. First, it is noted above that having no control is a condition where relevant feedback from any coping attempt is zero. But what would happen if the value of relevant feedback might fall below zero, becoming negative? This could occur if a coping attempt (avoidance-escape response) produced some aspect of the stressor rather than leading to a stimulus condition indicating absence of the stressor. In the first test experiment, avoidance-escape animals were required to perform a wheel-turning response to avoid and/or terminate a train of shocks but then negative relevant feedback for such responding was introduced by giving one brief pulse of shock immediately following any wheel-turning response. The results of this study, reported in Weiss (1971c), made clear that this condition was very detrimental; so much pathology developed when animals were forced to respond when relevant feedback from coping attempts becomes negative that animals could hardly survive this condition for 24 h. Next, as noted above, avoidance-escape responding in an unsignaled shock condition produces a low level of relevant feedback. Therefore, a manipulation was preformed to greatly increase relevant feedback in this condition. To do this, a brief auditory signal was added after every avoidance-escape response; because this signal is a stimulus always removed in time from the occurrence of shock, it represents a safety signal and greatly increases relevant feedback from responding in the unsignaled shock condition. The results of this study, reported in Weiss (1971b), showed that

simply adding this auditory signal for relevant feedback essentially eliminated gastric pathology, reducing it almost to the level seen in no-shock subjects that received no shocks at all. In summary, findings of these two experiments strongly supported the formulation shown in Fig. 4 and the underlying reasoning that led to it. Incidentally, these studies established that the rat’s receiving uncomfortable or even painful electric shocks throughout the procedure had almost no influence on the development of stress/gastric pathology; the severity of stress and pathology was shown to depend almost entirely on behavioral and psychological factors attending the shock situation and did not result from the shocks themselves.

The formulation shown in Fig. 4 can be used to account for the results seen in the “executive monkey” study. As described earlier, the “Sidman” avoidance schedule used in that experiment administered unsignaled shocks to the monkeys, and, for the monkey controlling the shock by pressing its lever, the relevant feedback from responses was therefore low. In fact, because shock in that experiment consisted of a train of very brief shock pulses each pulse given 5.0 s apart, the animal controlling shock could not even perform a clearly-defined escape response that demonstrably terminated shock – in contrast, every lever press by this monkey just postponed shock without producing any stimulus change in its environment, a condition of very low relevant feedback. Thus, a high rate of responding in such a condition is prone to high stress and pathology.

Additionally, an important detail regarding how the “executive monkey” study was conducted adds to its pathogenic potential. As also discussed earlier, the “executive monkey” study was not designed to examine the effect of having control versus no control, but, rather, was conducted to establish that preforming an avoidance response could lead to gastric pathology. Consequently, no attempt was made to equate the avoidance and yoked monkeys of each pair; instead, a yoked subject was simply paired with each avoidance monkey to insure that an animal not performing the avoidance response would receive an equal number of shocks in order to rule out the electric shock as having produced

the gastric pathology. Because of this, the experimenters used an unfortunate procedure: they set up both animals of each pair with an active lever at the outset of training, and let the animal that became the avoidance subject self-select itself by taking over avoidance responding. Within the first hours of the experiment, one monkey of the pair responded at a much higher rate than the second monkey, and so the high-rate responder was made the avoidance subject and the other monkey's lever was deactivated so that it became the yoked subject. This anomaly is crucial – as a result of this procedure, the “executive monkey” was designated as such because it responded at a high rate, and higher than its yoked subject. Thus, the monkeys that were made the “executive” were, because of their response tendencies, more prone to develop pathology than the yoked monkeys from the outset. And then these “executive monkeys” were placed into an ongoing situation where their responding produced very low relevant feedback. Consulting Fig. 4, this set of circumstances – high response rate, low relevant feedback from responding – is precisely the kind of situation that will result in pathology, and this is what indeed was observed in the “executive monkey” study.

More than 45 years have now elapsed since publication of the Scientific American article in 1972 titled “Psychological Factors in Stress and Disease” (Weiss 1972) which was relevant to the “executive monkey” experiment that had been published in the same Journal in 1958. Since then, a number of significant developments have occurred. First, the principles proposed in that article – i.e., that stress and pathology increases as (a) responses increase and (b) relevant feedback from responses decreases – has been embraced, applied, and reiterated in a number of fields, including, notably, industrial psychology (e.g., Karasek 1979; Siegrist 1996). Second, a large amount of research has established that having control over a stressful situation is more beneficial – i.e., results in less stress – than having no control, which is opposite to what the “executive monkey” study suggested (e.g., Gray 1998; Payne 2013; Sherman et al. 2012). This is now accepted as an accurate general conclusion. Third, it is often said that the

“executive monkey” results now have been falsified, debunked, as a result of the selection factor used to choose the “executive” monkey. For example, this is what was stated recently by Sherman and colleagues in Proceedings of the National Academy (Sherman et al. 2012). I respectfully disagree. The results of the “executive monkey” study have not been debunked; they are not erroneous. They are highly lawful and exactly what one would predict given the conditions that generated them. These findings are clearly explained in accord with the formulation shown in Fig. 4. What is correct to say is that the executive monkey experiment does not describe what one would expect to be the normal consequence of exerting control versus no control, but, rather, represents a highly unusual situation where exerting control was detrimental – because of the resulting high response rate, augmented by the avoidance monkeys being selected because of their high response proclivity, and the low relevant feedback from responding. Consequently, we now understand the findings in the “executive monkey” experiment and why negative consequences occurred for animals “in control,” and therefore these findings can be appropriately integrated into our knowledge.

## Concluding Comments

First, with the discovery, in the 1980s, of the pathogen *Helicobacter pylori* as an important factor in peptic ulcer disease, and the successful treatment of the disorder by antibiotics (Marshall and Warren 1984; Marshall et al. 1985), initially it was thought that any association of this disorder with stress was now disproven, and decades of previous study and theorizing in this regard were erroneous. However, (1) it was subsequently discovered that ulcer could develop and also recur in the absence of *H. pylori* (e.g., Laine et al. 1998; Tsuji et al. 1999), (2) it has been proposed that *H. pylori* is not the primary cause of ulcer but, rather, is responsible for a secondary infection that accounts for chronicity of ulcer disease (Tovey et al. 2001; Vikram et al. 2013), and (3) while prevalence of *H. pylori* infection is high across the

world (for example, present in 35% of the population in the U.S. [Hooi et al. 2017]), peptic ulcer disease is found in a much lower percentage of people (for example, present in 1.1–1.5% of the population in U.S. [Sung et al. 2009]), so other factors clearly must be present for peptic ulcer disease to occur. Thus, *H. pylori* infection is neither necessary nor sufficient for development of peptic ulcer. Also, stress has been shown to decrease bodily defenses against pathogens by decreasing protective immune responses including phagocytosis that controls gram-negative bacteria such as *H. pylori* (e.g., Glazer and Kiecolt-Glazer 2005), so stress may influence infection by *H. pylori*. Research throughout this period has continued to show that development of peptic ulcer disease requires hypersecretion of stomach acid. Fifty years earlier, Wolf and Wolff had shown that emotional upset led to gastric engorgement and increased stomach acid secretion in humans (Wolf and Wolff 1947). In summary, discovery of the significance of *H. pylori* for ulcer disease does not rule out an important role for stress in development of gastric and duodenal ulcer.

Second, while the writings of psychoanalysts on the topic of ulcer have been pushed aside for many years, this writer suggests that perhaps the work of perceptive psychoanalytic colleagues should not be summarily dismissed. Franz Alexander, in theorizing that many ulcer patients were hard striving individuals whose unconscious desire was, instead, to be passive and nourished, describes a high response rate, low relevant feedback condition leading to gastric pathology. Experimental research on animals described in this chapter provides a framework indicating that this particular condition is one of high stress and conducive to development of gastric pathology. That framework may integrate the data from these different sources; perhaps there is a surprising agreement here.

## Exemplar Theory

J. David Smith<sup>1</sup> and Barbara A. Church<sup>2</sup>

<sup>1</sup>Georgia State University, Atlanta, GA, USA

<sup>2</sup>Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

## Introduction

Understood psychologically, a category is a memory store that lets organisms behave consistently and adaptively toward ecologically equivalent objects that may have imperfect perceptual similarity. Animals' capacity for categorization has conferred fitness advantages on them for hundreds of millions of years. Indeed, some animals (e.g., vervet monkeys) have developed calls that denote or “name” members of threatening categories, thus warning conspecifics and allowing them to respond appropriately. Exemplar theory is an entrant into the sharp theoretical competition to provide the best psychological description of these category-knowledge stores.

## Definition

Exemplar theory's idea is that animals store separately the category exemplars they encounter (e.g., exemplars of predator eagles or durian fruits) as whole, individuated memory traces. Then they compare new items to these multiple memory reference standards and include the items in the category if they are similar enough to the stored exemplars. The key point is that the organism need not have, and may not have, a unitized, summary idea of predator eagle. Rather, it may have a slide carousel of eagles, a Rolodex of eagles, an iPhone playlist of eagles. It is an intriguing psychological theory that warrants careful consideration and evaluation.

## History of Exemplar Theory

Exemplar theory came to dominate the human literature in the 1970s, given a confluence of research findings and a particular scientific aesthetic. At the time, Rosch and others had developed the prototype comparison theory of family-resemblance categorization (Rosch & Mervis, 1975). Its idea was that minds average their experiences with natural-kind categories (like eagles) to produce a memory representation that is the central tendency or prototype of the category. This theory fit admirably the case of eagles, durian fruits, and many other natural kinds that are coherent families of perceptually similar objects. Indeed, as we will see, this theory may be the appropriate psychological account of animal categorization. However, Medin and his colleagues (e.g., Medin & Schaffer, 1978) realized that not all categories are organized by family resemblance and prototypy. Categories can also be defined logically (e.g., exclusive-or categories), randomly (who is in my foraging group today?), or for ad hoc reasons (items to pack in the car for a road trip!). Furthermore, Medin's research showed that humans can somewhat learn (but see below) logical, random, and ad hoc categories for which prototype-averaging processes will not work. Thus, we might need different psychological explanations for explaining the learning of different kinds of categories, ending with a messy, unparsimonious model of mind. Bear in mind that human and animal minds could be messy in just this way.

Defending parsimony, Medin proposed instead that one representational system might serve all categorization. Their elegant proposal was as already described, with many individuated exemplar memories used as the memory reference standards for categorization. It is not required in exemplar theory that *all* experienced instances be stored in memory. However, in many formulations of the theory, and in nearly all of exemplar theory's formal models, the allness assumption is obeyed. Over a lifetime, a vervet monkey's eagle playlist could grow quite large (leave aside humans' playlist of French fries).

Exemplar theory's dominance lasted for about 20 years (sustained especially through work by Nosofsky and his colleagues, e.g., Nosofsky, 1986). One can see why. The theory instantiated well the attractive aesthetic of parsimony in science, just as did the associative construct in comparative psychology. Exemplar theory made categorization unitary – categories of all kinds could be learned in the same manner by the same unitary system. There was only one exemplar-comparison process to understand. This unity possibly obviated the need to consider different kinds of categories, different category tasks, different learning strategies, different brain circuits, and possibly even different categorization capacities across species. In essence, all categories could be deemed equivalent and learnable. The exemplar theorists in particular fought the idea that family-resemblance categories were somehow better structured, more natural, more learnable, or psychologically privileged. This period in categorization science is intriguing because it shows how salient and guiding the principle of parsimony can become, perhaps even slowing empirical progress and veiling the psychological truth of the matter.

## Evaluation of Exemplar Theory

Exemplar theory has been evaluated along two dimensions: by the goodness of fit of formal exemplar models to categorization data and by the learnability of poorly structured categories unfriendly to prototype processes. Considering these two in turn, one sees that exemplar theory met with serious difficulties almost immediately.

### Model Fits

Regarding model fitting, exemplar theory's early successes that fed its popularity were limited in several ways. First, the categories tested contained small numbers of exemplars that were easily memorized, making them most amenable to exemplar processing. Possibly these "categorization" tasks were really stimulus-identification tasks, with participants rotely associating stimuli

to arbitrary labels with no sense of coherent categories (Blair & Homa, 2003). Second, the categories were poorly differentiated in similarity terms. Sometimes items were more perceptually like items in the opposing category than like items in their own category (Medin & Schwanenflugel, 1981). These categories – impoverished in family resemblance – possibly showed what humans do denied their natural approach to categorization, rather than showing their preferred exemplar approach at work. Third, the early studies used the scarce computational resources available (computers were just arriving on the scene) to fit the aggregated performance of whole participant groups. Averaging across individuals changes the character of psychological data – for example, by homogenizing away the high and low extreme performance levels on individual items produced by individual participants (Smith et al., 1997). For reasons beyond the scope of this entry, fitting averaged data systematically biases outcomes toward the exemplar model's good fit.

### **Learnability of Poorly Structured Categories**

Regarding learnability, humans performed very poorly on these early tasks that favored exemplar theory. In many experiments, about half of all participants never reached the learning criterion. Murphy (2003) warned categorization researchers about this problem. This failure to learn was problematic because it suggested that exemplar theorists were expressing the wrong psychology, or expressing a psychological competence that humans lack, or testing poorly structured categories in which humans cannot show their true categorization competence.

Accordingly, Smith and Minda conducted research (e.g., Smith & Minda, 1998) using well-structured family-resemblance categories that humans found more learnable. Now, many participants' data were fit better by a prototype model than by a closely matched exemplar model. In fact, the exemplar model made large, essentially disqualifying errors in these cases, in part because it mispredicted how strongly humans resonate to category prototypes. These results reminded the field that Rosch and others might have been

expressing an important insight about prototype processes in human categorization.

This was an important crossroads. The field might have acknowledged that alternative theoretical explanations like prototype theory still needed to be part of categorization's overall theoretical explanation. It might have narrowed the role of exemplar theory so that it applied to poorly structured categories with small, memorable exemplar sets. However, the attraction of the unitarian exemplar principle was too strong. Instead, mathematical variations and amplifications were added to the exemplar model to make it more powerful. In particular, modelers adopted the additional free parameter – gamma – that let the exemplar model manage more heterogeneous (spiky) data produced by individual participants. In some situations, gamma essentially enabled the exemplar model to imitate by mathematical artifice a prototype model. Readers must judge whether resuscitating mathematically a theory that is failing psychologically is a strong scientific approach.

### **Comparative Psychology Enters the Debate**

More recently, comparative research has made a transformational contribution to the evaluation of exemplar theory by rebalancing the theoretical literature back toward prototypes. One aspect of this contribution has been to illuminate the fundamental flaw with exemplar theory. The theory proposes the representation of multiple, disparate, and separate predator-eagle exemplars. These eagle exemplars – perceptually dissimilar – will be spread out like a cloud in the mind's psychological space. Therefore, exemplar theory predicts that even a perfectly typical item (e.g., a platonically ideal eagle) – precisely at the center of the category space – may still not be maximally endorsed into the eagle category, because it will still not be similar to all the stored eagles arrayed around it in memory space. Instead, it will always be close (similar) to some regions of the cloud but far (dissimilar) from others. Therefore, exemplar theory predicts that

even the prototype eagle will not generate a dramatically strong Eagle!-Hide! response.

## Monkeys

Rhesus macaques (*Macaca mulatta*) tested this prediction in Smith et al. (2008). The monkeys learned shape-distortion categories as shown in Fig. 1. These are family-resemblance categories (like eagles) – perceptually coherent, containing mutually similar instances and prototypical, typical, and less typical items.

Figure 2 (circles) shows the proportion of times a macaque accepted (endorsed) different instances into the category. We fit these data using a standard model instantiating exemplar processes. The model (Es) predicted lower performance on even the most typical item types, as dictated by the inherent geometry of exemplar memory spaces described above. It fit the monkey's data poorly – for example, sharply underpredicting the monkey's maximal endorsement of prototype items. The monkey apparently was not referring items to whole clouds of exemplars. Humans produce the same result as monkeys, disconfirming exemplar

theory in this task for both species (e.g., Smith & Minda, 2000).

If not exemplar comparisons, a competing possibility is that macaques average their exemplar experience to produce the category's central prototype. Then, when they experienced that prototypical eagle in nature, it would be indefinitely similar to their represented prototype and resonate terrifyingly strongly as an eagle. Testing this idea in Smith et al. (2008), a prototype model emulated a monkey's prototype processing. It was closely matched to the exemplar model except for assuming a unitary prototype comparison standard. The model's predictions (Ps in Fig. 2) were so precisely right that the Ps are hidden by the data points. Probably something like a prototype was the macaques' cognitive reference point, a conclusion reinforced by other studies (e.g., Aydin & Pearce, 1994).

Researchers have also tested exemplar theory by testing primates in prototype-exception tasks as described now. In Fig. 3, the eight shapes to the left and right are rewarded as Categories A and B, respectively – even though in each case the two bottom stimuli appear to belong to the opposing category. If exemplar theory is correct, monkeys should simply memorize the typical and exception items and categorize both item types correctly. However, if monkeys naturally assume prototype categories organized by family resemblance, they will systematically miscategorize the exceptions, placing them wrongly into the categories that maximize perceptual similarity and family resemblance. This tendency should result in poor, even below-chance exception-item performance.

Figure 4a–c shows three macaques' performance in this task (Smith et al., 2010). The macaques systematically miscategorized the exceptions, performing them below chance for thousands of trials. They did so even given hundreds of attempts at these trials – there were only four exceptions to memorize. To the contrary of exemplar theory's prediction, they exhibited a very weak capacity to store individuated exemplars and respond to them appropriately. This may imply that their exemplar capacity is not nearly developed enough to be relied on for all the

**Exemplar Theory, Fig. 1** Dot-Distortion Category. (Note. The originating prototype (P), low-level distortions (L), high-level distortions (H), and random-unrelated shapes (R) in the top to bottom rows, respectively. This category illustrates the idea of a family-resemblance category, with a typicality gradient running from the central prototype outward. **Exemplar Theory, Fig. 4** (a, b, c) Performance by Three Macaques in the Category Task of Smith et al. (2010). (Note. Curves T and E, respectively, show the proportion of correct responses made to the six typical and two exception items in each category. From “Stages of Category Learning in Monkeys (*Macaca mulatta*) and Humans

(*Homo sapiens*),” by J. D. Smith, W. P. Chapman, and J. S. Redford, 2010, *Journal of Experimental Psychology: Animal Behavior Processes*, 36, p. 48. Copyright 2010 by the American Psychological Association. Reprinted with permission)

important tasks of categorization. Instead, they apparently chose a persistent strategy based on prototypes and family resemblance. In this strategy, miscategorizing the exceptions *technically* is categorizing them *correctly* according to family resemblance. Humans produce similar results (Smith & Minda, 1998). Smith (2014) described the important evolutionary and fitness implications that follow from primates’ default strategy.

Yet one also sees that two macaques finally showed some mastery of exceptions. So we can grant them some late-breaking exemplar competence and acknowledge some role for exemplar memory in primate categorization. In the end, more than one process may support animals’ and humans’ categorization. Categorizing minds may actually be messy minds, an idea with which this entry began.

## Pigeons

Cook and Smith (2006) extended these findings and conclusions further across the vertebrates and by possible implication farther back through vertebrate evolution. They gave pigeons (*Columba livia*) prototype-exception tasks. The tasks presented color disks (not reproducible in this volume) with sectors of six different colors. The disks within a category had six typical colors (the category prototype), five typical colors (the typical items), or one typical color (this exception disk contained five typical colors of the technically opposing category). Cook and Smith found that pigeons – exactly as rhesus monkeys – systematically cross-categorized the exception items into the categories that would maximize perceptual family resemblance. A standard exemplar model fit pigeons’ data poorly. For reasons already

discussed, it could not predict how strongly they performed the prototypes or how poorly they performed the exception items they should just have memorized. Wasserman et al. (1988) found a converging result that they also supported through formal modeling.

Late in learning, the pigeons did develop some competence in learning/memorizing the exceptions so as to get them technically correct. Humans showed the same pattern of results early and late in learning. In fact, the cross-species graphs in Cook and Smith (2006) reveal a striking continuity in the processes of categorization across far-separated vertebrate species. Broadly across species, vertebrates seem to present with the same default prototype approach to category tasks, with a residual and weak exemplar capacity after extended training. However, in this consistent pattern, exemplar theory has only a narrow application and plays only a minor role.

In fact, this minor role may not even be biologically or fitness relevant. If the world contained exception eagles as tested in Cook and Smith (2006) or Smith et al. (2010), vervet monkeys would never survive the hundreds of error attempts they seem to need to memorize them. They would not survive a week. But there apparently are not exceptional eagles (i.e., eagles in sheep's clothing). Smith (2014) described the beautiful convergence between primates' true categorization competence (a prototype and family-resemblance competence) and the structure of natural kinds in the natural world (a prototype and family-resemblance structure). Perhaps this convergence is not accidental. It could have been sculpted by cognitive evolution.

### Exclusive-Or Tasks

Finally, researchers have tried to isolate the exemplar-memory process, forcing the animal's reliance on it so that its potency can be directly assessed. To that end, Smith et al. (2011) tested macaques in exclusive-or tasks. In this task, Category A and B items are split into subcategories and placed into opposite diagonal corners of their perceptual space (e.g., Category A members bottom-left and top-right in the space; Category B members top-left and bottom right). Here,

averaging the exemplars experienced into prototypes will fail because the A and B prototypes will be coincident in the center of the stimulus space. The prototypes will be useless to A vs. B categorization. Moreover, the two subgroups of A items (and B items, too) will not be perceptually similar to each other at all, defeating strategies based on family resemblance. So, this task structure leaves standing alone the forced categorization strategy of exemplar memorization.

Smith et al. (2011) gave macaques two-, three-, and four-dimensional XOR tasks. They found these tasks lacking prototypicality and family resemblance very difficult. Monkeys only reached about 75% accuracy. They erred on about a third of all trials. They received 15,000 20-s timeouts during this experiment. Contrary to the predictions of exemplar theory, and even when the task really only allowed the exemplar strategy, monkeys showed a minimal capacity to memorize and respond differentially and appropriately to individual exemplars. The exemplar capacity was absent without theoretical leave.

### Conclusion

In the end, human and animal evidence disconfirms an exemplar theory that purports to be a sufficient psychological explanation of categorization. Humans and animals display a robust prototype-abstraction capability. This prototype capability has apparently spanned more than 100 million years of vertebrate cognitive evolution encompassing birds and primates. It is likely that this prototype approach to categorization must carry the theoretical weight in explaining animal categorization. In contrast, exemplar-memorization processes in categorization – to the extent they are seen – are weak, hesitant, late-developing, and perhaps not biologically relevant. Murphy (2016) concluded that important phenomena in the psychology of concepts have no proposed exemplar explanation and that it is difficult to understand how an exemplar theory could be adequate. He wondered: "Is there an exemplar theory of concepts?" And yet there will certainly be times when animals face the need for

individuated exemplar traces, as when they learn their social group's dominance hierarchy. Therefore, it is premature to write exemplar-memorization processes off altogether for some cognitive purposes (although identifying alpha individuals is more specific-item recognition than it is categorization). Accordingly, the working consensus in the literature is that exemplar theory is discredited, but exemplar processes are sometimes in play. We can tentatively adopt a mixed idea of categorization that humans and animals have multiple categorization processes that manage the cognitive demands of multiple kinds of categories.

### Coding DNA

## Definition

Exons are the coding part of genome, which retained in the finally processed transcript and being translated into protein.

## Introduction

Exon is a part of the nucleic acid that is finally spliced together in the mature transcript and has the information for protein synthesis. The term “Exon” was first used by American biochemist Walter Gilbert in 1978. Richard J. Robert and Phillip A. Sharp independently discovered the split gene in the year 1977. The split or interrupted genes (in most of the eukaryotic genes) are those

genes in which the noncoding part, i.e., intron is present in between coding exons (Alberts et al. 2015; Gilbert 1978; Watson et al. 2004). The term “exon” is also used for rRNA, tRNA, and different genomic regions which are ligated by the transsplicing. Both the intron and exon part of the DNA are transcribed into the RNA which is heterogeneous and nonfunctional. This pre-mRNA undergoes the process of splicing in the nucleus in which noncoding part or introns are removed and the coding exons are ligated into a functional RNA. Exons of a gene are joined covalently in functional mature mRNA (transcript). The transcript after splicing is exported to the cytoplasm for translation. Exons are present in the genes of all eukaryotic organisms but absent in the genome of prokaryotes. New exons are originated by the mutation in the existing intronic sequence, termed as exonization, which is evident in the genomes of human, mouse, etc (Fig. 1) (Alberts et al. 2015; Gilbert 1978; Karen et al. 2010).

## Molecular Tools for the Characterization of Exon

1. **Exon Trapping:** Exon trapping is a technique to identify expressed part, i.e., exon in any fragment of DNA. In this technique, DNA

**Exon, Fig. 1** Upper panel shows organization of split gene with exons (coding DNA) interrupted by introns (noncoding DNA) which transcribed into primary transcript (pre-mRNA), contains exons and introns. By

splicing, noncoding introns are removed and coding exons ligated to form mature transcript which is being translated into polypeptide chain

**Exon, Fig. 2** Figure showing the cloning of DNA fragment (with and without exon) in a splicing vector. After splicing only exon parts trapped in the final transcript while the intron parts spliced out

fragment of analysis first cloned in between two exons in a splicing vector (exon trap vector). If the cloned part contains intron only then will be spliced out in the final transcript. The exon part will retained which can be analyzed by PCR (Fig. 2) (Wapenaar and Dunnen 2001).

2. **Exon Array:** Exon array is the type of microarray in which specific oligonucleotide probes are used to target specific exon combination or alternative splicing pattern in the mixture of transcripts. The probes are designed in such a manner that a particular transcript can be picked up if it is undergoing alternative splicing. This method is also used to study tissue specific expression of protein isoforms of a gene. Different labelling protocols in exon array method are required to avoid contamination from the other RNA species as rRNA and tRNA (Majewski 2009).
3. **Exome Sequencing:** Exome term refers to the entire set of exons of an individual. In the human genome, only 1% part constitutes the exons, remaining part is noncoding intron and intergenic DNA, thus exome sequencing is cheaper and convenient than whole genome sequencing. Exome sequencing is useful to study gene expression and pathology of various diseases but it is not suitable to study regulation of gene expression by the noncoding RNA and DNA (Warr et al. 2015).

**Exon Shuffling:** Exon shuffling is the recombination between noncoding introns which results

in assorting of exons from different gene, leading to the formation of new gene structure. Exon shuffling occurs by three modes, i.e., exon duplication within the same gene, exon insertion, and deletion from the different gene. Exon shuffling is another mode of generation of new genes as around 19% of exons have been reported for exon shuffling. The exon shuffling was first reported by Walter Gilbert in 1978 in blood coagulation factors, which is now evident in many multidomain proteins. Exon shuffling also results in the altering the function of proteins and evolution of new protein family. The recombination generally occurs in the noncoding intron as they are longer and contains transposable elements and repetitive sequences. Existence of mosaic proteins in which protein domains from a gene are present in another gene product provides evidences of exon shuffling (Jonathen 2013; Hillstrom).

**Exitron:** Exitron are exon-like intron retained in the final transcript and translated into protein part. The splicing of exitron impaired the protein structure and function. They are well reported in plants and metazoan transcriptome. Exitron are produced due to alternative splicing (Marquez et al. 2015).

## Conclusion

Exons are the protein coding part of DNA and its transcribed RNA which are interrupted by the noncoding introns. These noncoding introns are

spliced out and coding exons are ligated by the process of splicing during posttranscriptional processing. Thus the exon is the section of genome which is expressed into proteins. Exon trapping is a technique of gene identification and characterization. By exon trapping we can identify whether an expressed part, i.e., exon present in any fragment of DNA or merely an intron sequence. In exon shuffling, recombination occurs between intronic regions so that coding exons from different part of genome come together and translated into mosaic proteins. Sometimes mature mRNA may contain retained intron within the exon termed as exitron which functionally affect the outcome of the gene expression. Splicing can be targeted or modulated by the use of morpholino or blocking snRNPs so that different combination of exons can be included in the final mature transcript.

Neurosciences, Bangalore, India

## Synonyms

[Trinucleotide repeat expansion diseases](#); [Trinucleotide repeat expansion](#); [Triple repeat disorders](#)

## Definition

Dynamic instability of trinucleotide repetitive sequences (CAG or CGG) in the coding or non-coding regions of the genome and its expansion and epigenetic changes followed by paternal or maternal transmission to the next generation cause different neurological and muscular diseases.

## Introduction

In the large human genome, different stable repeat sequences are present at different levels with its significant role. Since 1991, the potential for apparent genomic instability was unsolved when an expansion of one of these repeats, a trinucleotide (CAG) repeat (TNR) in the gene encoding androgen receptor, was discovered in patients with spinal and bulbar muscular atrophy

**Expanded Triple Repeat, Fig. 1** Unstable TNR in different diseases (Science Daily Nadine Ben, 4 Jan 2017)

E

(a neurodegenerative disorder) (La Spada and Wilson 1991). In normal condition, there are 13–30 CAG repeats, whereas in patients, it lengthens up to 40 or more. In the progressive year, more than 20 disorders have been reported with the TNR expansion. Unlike other conventional mutations, this mutation is dynamic because the expanded repeats undergo further changes in subsequent generations. The magnitude of the expansion is related to parental repeat length. Although mammals have developed different systems to resist the unexpected rapid deleterious repeat sequences in their genome, beyond a crucial threshold length, this TNR breaks down the barrier and expands during parent-child transmission and the progeny development (Fig. 1).

## Classification

Disorders of this repeat expansion can be either in the (a) noncoding region of the genome or (b) coding region of the genome. Noncoding region repeat expansion causes a loss of gene function or toxic effect at the mRNA levels, and in case of coding regions, it results in an expansion of polyglutamine or polyalanine tracts in the protein product causing the protein to become toxic with or without loss of function.

Loci that undergo repeat expansion can be classified into two groups based upon their repeat, either the CGG repeats or CAG repeats. The CGG/CCG repeats are found in noncoding region and associated with chromosome fragile site whereas CAG/CTG repeats are most often found in coding region and associated with

neurodegeneration (exception myotonic dystrophy). CGG repeat can be of massive expansion of thousands of normal length of 30 repeats, whereas CAG repeat is of more modest two- to threefold of normal length of 20 repeats (Fig. 2).

## Noncoding TNR Expansion

Noncoding TNR includes CGG, GCC, GAA, CTG, and CAG. The pathophysiology of the related disorders lies on its particular repeat types and its location in the gene.

### Friedreich Ataxia (FA)

The most common hereditary ataxia (autosomal recessive) bears homozygous GAA repeats in intron 1 of the gene frataxin (210aa Frataxin) resulting in abnormal mRNA and protein production. Accumulation of mitochondrial iron (Fe-S cluster deficiency) causes increased susceptibility to oxidative stress due to decrease in oxidative phosphorylation. Clinical features include cardiomyopathy, renal failure, diabetes, myocardial infarction, thinner spinal cord, selective atrophy of large neurons, synaptic modification, etc. Diagnostic criteria are ataxia of the limb and gait, dysarthria, extensor plantar response, type I hereditary sensory, and motor neuropathy.

### Fragile X Syndrome (FMR1/FRAXA)

This is caused by an expansion of CGG repeat (230–1000 in full mutation compared to 6–52 copies with interspersed AGG repeats in normal) in the 5'UTR of fragile X mental retardation (FMR1) gene. Nonstaining gap of fragile sites on human metaphase chromosome (Xq27.3) which are cytogenetically visible is known as

**Expanded Triple Repeat, Fig. 2** Different types of TNR expansion (Science Daily Nadine Ben, 4 Jan 2017)

FRAXA (fragile site, X chromosome A site). This is most frequently associated with mental retardation. In an X-linked dominant inheritance pattern, it is showing reduced penetrance of 80% in male and 30% in female (Sherman paradox) (Sherman et al. 1984, 1985) where normal allele and permuted alleles are unmethylated, whereas full mutation CCG repeats are methylated, and this methylation is the most sensitive indicator of penetrance. Learning disabilities and mental retardation (IQ level 20–70) with ataxia or tremor are diagnostic clinical features. 20% male and 5% female patients show seizure, and some of them show obsessive compulsive disorder and self-injurious activity.

Other folate-sensitive FMR1 but negative FRAX includes **fragile X E, F (FRAXE, F)** and **fragile 16A, 11B (FRA16A, 11B)**.

#### Myotonic Dystrophy (DM)

In an autosomal dominant fashion, human chromosome 19q13.3 was identified for displaying length variation like 50–3000 CTG repeats in the 3'UTR of serine-threonine kinase (DMPK, DM kinase) in DM patients (Brook et al., 1992) compared to 5–37 in normal caucasian. This repeat is associated with muscular dystrophy in those patients. Altered chromatin structure associated with DM TNR and unusual nuclear sequestration

has been reported from muscle biopsies and affected fibroblast (Taneja et al. 1995).

#### Coding TNR Expansion (CAG/CTG)/ Polyglutamine Expansion

The CAG expansions are present in the coding region of a gene, which when transcribes and translates produces polyglutamine which is misfolded due to aberrant protein interaction and acquired toxic features by losing protein degradation via ubiquitination causing selective neuronal loss.

#### Spinal and Bulbar Muscular Atrophy (SBMA)/ Kennedy's Disease

It is an X-linked recessive adult-onset motor neuropathy (Kennedy et al. 1998; La Spada and Wilson 1991). In the Xq12 site, the androgen receptor (AR) contains a TNR (38–66 CAG) within the first exon encoding polyglutamine tract (PGT) compared to the normal 11–33 causing meiotic instability in transmission (La Spada et al. 1992). In affected sperm, there is 60% expansion, and 15% contraction in AR has been found (Zhang et al. 1995). Altered AR gene expression causes neuron degeneration and incomplete androgen sensitivity including gynecomastia, reduced fertility, and testicular atrophy as well as gain of function resulting in

selective motor neurotoxicity due to lower motor neuron degeneration (loss of brainstem nuclei resulting in proximal muscle weakness and fasciculation, bulbar muscle dysfunction like dysphagia).

Spinocerebellar Ataxia, Type 1 (SCA1)

SCA1 is an autosomal dominant neurodegenerative disease. A CAG repeat (41–81 in comparison with normal individual 6–39 repeats) on chromosome 6 was identified in the SCA1 (codes for 87 kD ataxin protein) region by Orr et al. (1993). An inverse correlation between repeat length and age of onset has been documented, whereas direct correlation between repeat length and severity of disease is present. Juvenile cases are mostly due to paternal along with maternal transmission. The presence of cryptic interrupting CAT repeats in 13th and 15th position of CAG repeats in normal population is important for maintaining the genomic stability. Clinical features include progressive limb and gait ataxia, dysarthria, dysphagia, ophthalmoparesis, muscle wasting, and peripheral neuropathy including loss of Purkinje cells of the cerebellar cortex, atrophy of the brainstem, and neuronal loss in the cerebellum, brainstem, and spinocerebellar tracts.

SCA6, 7, 8, 12, and 17 are the other few types of spinocerebellar ataxia.

Huntington’s Disease (HD)

Huntington’s disease is an autosomal dominant movement disorder characterized by neuronal

loss (primarily of medium spiny neurons) in the caudate and putamen. Following the description by George Huntington in 1872, this disease is named as Huntington’s disease. An unstable CAG repeat (36–121) in HD patients, encoding a PGT in the It15 gene (348 kD huntingtin protein), is present compared to 10–35 (normal). Predominant paternal transmission in juvenile cases is very common with the presence of permutation allele like FXMR. Characteristic features include progressive cognitive decline, chorea, and movement impairment.

Huntington’s disease like2 which is another CTG TNR expansion related to neurological abnormalities is also reported.

Dentatorubral-Pallidoluysian Atrophy (DRPLA)

DRPLA is an autosomal dominant disease named for the neuropathological findings of atrophy of the dentate nucleus of the cerebellum and its projections to the red nucleus (rubro) combined with atrophy of the lateral segment of the globus pallidus and its projections to subthalamic nuclei. 7–25 CAG repeats (normal) with expansion to 49–75 repeats in affected individuals and repeat expansions are more frequently observed in paternal transmissions. Clinical features include cerebellar ataxia, choreoathetosis, and dementia, although patients <20 years old show progressive myoclonic epilepsy and mental retardation.

**Haw River Syndrome (HRS)**

It is an autosomal dominant neurodegenerative disorder (CAG TNR 63–68) prevalent in a single African-American family from Haw River, North Carolina (Farmer et al. 1989).

**Machado-Joseph Disease (MJD/SCA3)**

The disease was initially described in individuals of Portuguese-Azorean descent (Nakano et al. 1972), now recognized as SCA3. The CAG

TNR (12–37) is present in MJD1 gene in normal, whereas affected individuals contain 61–84 repeats. Degenerative changes have been noted in the neurons of the substantia nigra, dentate nucleus of the cerebellum, spinocerebellar and pyramidal tracts of the spinal cord, and peripheral neurons. Clinical features like cerebellar ataxia and extrapyramidal features include dystonia-rigidity reminiscent of parkinsonism, peripheral

neuropathy, facial and lingual fasciculation, and external ophthalmoplegia (Table 1).

#### Polyaspartic Acid Repeat

Mutations in the COMP (cartilage oligomeric matrix protein) gene in patients with multiple epiphyseal dysplasia.

### Therapeutic Approach

The development of therapeutics also varies for the noncoding and coding disorders. For noncoding disorders, restoring gene function or compensating for the loss of function is the major focus, whereas coding is directed toward ameliorating the consequence of the toxic protein.

### Conclusion

An acute and sophisticated mechanism maintains the stringency and stability of human genome and also in subsequent generations. Disruption of stability in the genome causes malfunctions and executes its effect in the form of disease. Repeat sequences are present in the genome normally in the form of micro- or minisatellite, triple repeats, etc. After exceeding a certain threshold level, the triple repeat can be toxic for the cell. Triple repeat can be in either noncoding or coding region in the form of CCG or CAG repeat, respectively. These repeats are expanded in subsequent generations and execute their effect when it transmits paternally or maternally, in the form of mental retardation, movement disorder, reduced fertility, etc. Different therapeutic interventions are under clinical trial targeting the pathomechanism of the disease. Most of the drugs are either in the form of antioxidant, transcriptional suppressor, demethylating agent, apoptosis inhibitors, etc. The in-depth knowledge of the pathomechanisms and the cryptic genetic mechanism related to these diseases will help in the further progression of the amelioration of these diseases.

## Experience Projection

Cathal O'Madagain

Department of Developmental and Comparative Psychology, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany

### Definition

Experience projection is the ability to use our own past experiences to attribute experiences to others in similar situations. A task proposed by Cecilia Heyes to test the ability has become a landmark for investigating mind-reading abilities in other species.

### Introduction

Suppose you look out the window and see a new car in the driveway. Moments later you notice me looking out the same window, and you draw a conclusion: that I must be able to see the new car in the driveway. In doing this, you are using your past experience to draw a conclusion about what I can see. You have “projected” your experience of looking out the window to me. Since seeing is a mental state, such an attribution is a form of “mind-reading” – the activity of discerning the mental states of others. It has become a focal point for psychologists aiming to establish mind-reading in other species.

### Knowing About Other Minds

How do we figure out what is going on in others' minds? The striking thing about other minds is that we can have no direct experience of them ourselves – they are “invisible” (Locke 1690/1975 111.ii.1). All that we have to go on is the

behavior of others to decide what, if anything, they are thinking. For this reason, an early account of how we generate beliefs about other minds is that we do so through an “analogical inference” from our own experience (Mill 1865). On this view, when we see others behave in familiar ways, we attribute to them the mental states (experiences, beliefs and desires) that we ourselves have when we behave in those ways. We could say that this straight-forward account of mind-reading amounts to a description of what has more recently been called experience-projection.

In experience-projection, we take our own past experiences and use them to form beliefs about others' experiences. The notion of “experience” is broad here and can include a whole range of mental states including what someone can see, what they can hear, what they might believe, or what they might desire. Since this kind of reasoning involves mental state concepts like “sees” or “believes,” experience-projection is a kind of mind-reading. In addition to being central to the “analogical inference” account of mind-reading, experience-projection plays a central role in “simulationist” accounts of mind-reading (Goldman 2006), while “nativist” accounts (Leslie et al. 2004) or theory-theory accounts (Gopnik and Meltzoff 1997) do not assign a central role to this kind of reasoning.

The fact that all we have to draw on when mind-reading is the behavior of others, however, generates substantial philosophical puzzles for our knowledge of other minds. For example, since behavior is only indirect evidence of mental states, some have doubted whether our beliefs in other minds can ever be properly justified (Ryle 1949, 15); and since we can have no direct experience of others' mental states, we can also doubt whether the concepts we use to think about others' mental states are ever appropriate (Nagel 1974). That all we have to draw on is others' behavior to engage in mind-reading also generates difficulties for experimentally testing mind-reading abilities in other species. If every instance of mind-reading is also an instance of behavior-reading, then any observation of apparent mind-reading in another species will also be an observation of behavior-reading. This raises the worry that any experiment

that appears to illustrate mind-reading in another species may always be interpretable as illustrating no more than behavior-reading.

To see the problem, consider the “guesser-knower” paradigm, designed to experimentally illustrate mind-reading in nonverbal creatures (Povinelli et al. 1990). Here, participating chimpanzees (*Pan Troglodyte*) are presented with two agents, one with a bag over her head (the guesser) and one without (the knower). Food is hidden in containers by a third agent, in such a way that the “knower” sees the hiding but the guesser does not. All of this is observed by the participating subject. The guesser and knower now each point to different locations, and the participant can pick one of these locations to search for food. After a number of trials, the apes reliably prefer to search the location indicated by the “knower.” The authors took the results to illustrate a recognition of the difference between a knowledgeable and an ignorant agent on the part of the apes, and hence to illustrate mind-reading. However, the setup is vulnerable to a clear behavior-reading alternative. The “guesser” and “knower” are visually distinct – the guesser wears a bag over her head, the knower does not. And so the results are ambiguous, as the authors came to recognize. On the one hand, they might show that the apes understood that one agent could see the food being hidden and the other could not – a “mind-reading” interpretation; but they could also simply show that the apes learned that the agent without a bag on her head was more likely to be pointing at the location of food – a “behavior-reading” alternative (Heyes 1998, 106).

### Experience Projection as a Solution to the Behavior-Reading Confound

To disentangle mind-reading from behavior-reading, Heyes (1998) proposed an “experience projection” paradigm. The aim of the paradigm is to capture subjects evaluating the behavior of an agent differently depending on what they have themselves experienced in the past. In one condition, subjects have had the experience of being in the position of the agent they observe, and in the other condition they have not had that experience.

If subjects form different expectations depending on their own past experience, it seems that this can only be explained by the subjects projecting their own past experience to the agent they observe. Particularly, since the observed agent’s behavior would be identical in both conditions, it seems that there is no behavior-reading alternative that participants could be using to form their expectations.

Heyes presented the idea as a hypothetical paradigm we can call “the goggles experiment.” In this setup, subjects first get to have experience with two pairs of goggles. Both pairs of goggles look as though they are opaque from far away, but when worn, one of the pairs turns out to be see-through. Participants now get to watch someone else wearing the goggles. This agent provides the participant with pointing gestures to indicate the location of hidden food, while wearing either the opaque or the see-through goggles. What we should expect is that participants who have had experience with the goggles and can attribute states of “seeing” or “not seeing” to the agent will follow the gestures of the agent wearing the see-through, but not the opaque goggles. A control group of subjects is also presented with the pointing behavior from the agent wearing goggles, but has no prior experience with the goggles themselves. Participants who have had no experience should not make this distinction.

If the participants who have had experience pay more attention to the agents wearing the transparent goggles than the agent wearing the opaque goggles, there seems to be only one explanation for how they could do this. This is that they have drawn on their own past experience with the goggles, and they have used this experience to attribute states of “seeing” or “not seeing” to the agent. Since the concept “seeing” is a mental concept, this would illustrate mind-reading on the part of the subjects. And since the behavior of the agents the participants observe is identical, we seem to have demonstrated mind-reading while eliminating the behavior-reading confound.

In addition to promising to eliminate the behavior-reading confound, the paradigm has the potential to capture the most intuitively clear kind of mind-reading – the “analogical inference” articulated by Hume, which is really what

experience-projection amounts to. Heyes' proposal is therefore both experimentally and conceptually very appealing.

## Experimental Progress

Meltzoff and Brooks (2008) conducted a study along the lines of this proposal with 18-month-old infants. They used blindfolds that both looked opaque from a distance, but one of which blindfold could be seen through when held close to the face. Children participated who either had experience with the properties of the blindfolds or had no experience. The authors found that children who had experience with the "see through" blindfolds would follow the gaze of an experimenter wearing one of these more than they would follow the gaze of an experimenter wearing one of the opaque blindfolds; while the children that did not have experience with the two kinds of blindfolds showed no preference to follow experimenters wearing the transparent blindfolds. This seems to indicate that at 18 months, children can engage in mind-reading by experience-projection.

Vonk and Povinelli (2011) report a similar experiment with chimpanzees, but found no positive result. This time buckets were used, either transparent or opaque. Apes with experience of the see-through buckets displayed no preference to follow the gaze of an experimenter wearing a see-through bucket over one wearing an opaque bucket. Karg et al. (2015) also found a negative result for chimpanzees in a similar gaze following task. However, these authors then introduced a competitive element to the experiment, drawing on the finding that chimpanzees are often more motivated and skillful in competitive than cooperative contexts (Hare and Tomasello 2004). Chimpanzees were given the opportunity to interact with two boxes. Both boxes have lids that are opaque when viewed from an angle; but the lid of one of the boxes, when viewed directly, is transparent. The chimpanzees are now placed opposite an experimenter who will remove food from a box that the chimpanzee tries to extract food from – in effect acting unhelpfully or competitively. The experimenter is viewing the lids of the boxes

directly and hence can see through one of them, while from the chimp's position both lids appear opaque. What was found is that the chimps that had experience with the see-through lid avoided taking food from the box fitted with that lid, apparently to avoid taking food that an experimenter can see. This indicates that the chimps are indeed drawing on their own prior experience to make a decision about which box to try to take food from, and are attributing mental states of being able to see or not being able to see to the experimenter.

We also have evidence for the convergent evolution of experience projection in other species beyond our close cousins the chimpanzees. Emery and Clayton (2001) have found that corvids can also pass a version of the experience-projection task. Scrub Jays (*Aphelocoma coerulescens*) were given the opportunity to "cache" or hide food when a second bird is either watching them or not. They were then allowed to subsequently return to the enclosure to retrieve their food, without the observing bird. It was found that the birds who had been watched by another bird were more likely to re-cache their food in a new location when they had the chance than those who had not been watched. Importantly, the authors found that the birds who had themselves previously played the role of observer and then attempted to pilfer another's food were more likely to move their food to a new location when in private than those who had never played the role of observer. This suggests that having had the experience of observing another bird caching food, Scrub Jays can draw on this experience to pick a strategy when hiding their own food. This would again count as an instance of experience-projection, since it would appear to require the birds to evaluate what the observing bird can see on the basis of what they saw themselves in the past.

## Criticism of the Paradigm

Lurz (2009) argues that the experience projection task is flawed – that there remains a behavior-reading alternative that is not ruled out. The

behavior-reading alternative is that a participant might solve the task by simply tracking whether another either has or lacks a “line of sight” on some object. Since a line of sight is simply a geometric line in space between an agent’s eyes and some target, the concept is not essentially mental, and hence if the task can be solved in this way, it would count as a behavior-reading alternative. Lurz argues that the task could be solved in this way by the agent who gains experience with the goggles by recognizing that when the transparent goggles are worn, the wearer has a direct line of sight on objects in her environment. When the opaque goggles are worn, on the other hand, there is no direct line of sight. This should be enough to get the subject to follow an agent’s gaze when the agent wears the transparent but not the opaque goggles, or to steal food when the opaque but not transparent goggles are being used. But it would not involve any mental concepts on the part of the subject.

Whether this critique is sound is unclear. It requires us to believe that the subject takes the agent she observes as having nothing occluding her vision when she is wearing the transparent goggles. But this is hard to believe – it is immediately obvious that an agent wearing transparent goggles has something occluding her vision – namely the goggles. The reason we understand that an agent wearing the transparent goggles can see is not because she has nothing in her line of sight, but rather because the object in her line of sight is transparent. And the very idea of transparency is itself a notion that cannot be separated from the mental concept of seeing: “transparent” simply means “see-through.” Doubtless, we will benefit from having further experimental setups that can illustrate mind-reading in other ways, as multiple lines of evidence are always more convincing than just one. Recent success with implicit false-belief tasks in chimpanzees illustrate that other ambitious mind-reading experimental setups can indeed succeed (Krupenye et al. 2016; Buttelmann et al. 2017). But the experience-projection paradigm remains an extremely important contribution to this family and should not be discarded just yet.

## Exploratory Behavior

Wojciech Pisula  
Institute of Psychology, Polish Academy of  
Sciences, Warsaw, Poland

Exploratory behaviors in animals involve various activities, such as moving antennae or raising ears, fixating gaze, moving from one place to

another in space, manipulating objects, sniffing, sensing, etc.

The best known and the most widely accepted definition of exploratory behavior was first put forward by Berlyne (1962), who defined exploratory behavior in terms of its function: “The function of exploratory responses is to change the stimulus field” (p. 286).

Marler and Hamilton (1966, p. 159) began their chapter on *Exploration, Aggression, Conflict and Play* with the following statement: “Animals spend much of their time in motor activity, the function of which is often difficult to identify.” Twenty-eight years later, when writing about exploration, Keller et al. (1994, p. 3) stated: “. . . we have not attempted to arrive at a definition of curiosity and exploratory behavior upon which every contributor to this volume would agree. Given the state of the art in research and theory on curiosity and exploratory behavior, we thought to attempt to do so would be counterproductive.” It seems that the difficulties with defining exploration are due to the many forms of behavior that different authors label as “exploration.” Some of these behavioral forms are described below from the least to the most complex.

**Taxes and Orienting Reflex.** These terms describe any turning of the body in relation to the position of the specific stimulus. Orienting reflex is synonymous with taxis. This term, however, is most often used with reference to less advanced organisms. In Pavlovian terms, an orienting response means any response involving paying attention to a stimulus, such as head turning or ear raising. Any reference to information seeking stresses the animal's own activity. However, any organism's fundamental reaction to external information is responsive in nature, since it involves a reaction to a stimulus received from the environment. This is a characteristic feature of the taxis and the orienting reflex observed in vertebrates. This reflex is released by a sudden, unexpected stimulus (“unexpected” from the point of view of the organism concerned). Information seeking in response to a stimulus is mostly aimed at finding its source: it is a strictly short-term response of an organism to a clear, unexpected sensory stimulus. The

orienting reflex is a behavior typical of vertebrates.

**Perceptual Exploration.** This refers to a prolonged perception, by any sensory system, of a specific stimulation – a direct extension of the orienting response. Perceptual exploration is strictly linked to focusing attention on the object perceived.

**Locomotor Exploration.** This refers to a situation where an organism is moving within or approaching a novel environment. The term “patrolling,” on the other hand, is often used to describe movements through a well-known area, usually the animal’s own territory. It involves “covering” the area available to the animal, while its main purpose is to obtain topographical information about the animal’s surroundings. This manner of gathering information develops in animals with the ability to form representations of the space that they inhabit.

Locomotor exploration is a one of the three main forms of exploratory behavior, along with orienting and investigatory reflexes. This general categorization inevitably places many different forms of behavior under one category. One of the forms of locomotor exploration is patrolling behavior, which involves systematic traversing of a familiar space, usually the animal’s own territory. An animal that inhabits a given environment forms a representation of its surroundings. Such mental representations may have varying degrees of complexity and include objects with well-recognized features. They can also include poorly defined objects, in which case the structure of representation will be very simple. Tolman (1948) put forward a hypothesis that the function of exploratory behavior is to construct a cognitive map. This was probably the first scientific attempt at analyzing animal behavior in terms of gathering information at the cognitive level.

Later studies by Tinbergen (1951) further illuminated the issue of cognitive maps. In his seminal research on digger wasps, Tinbergen demonstrated that animals seek specific information. They usually look for “landmarks” in terms of spatial orientation and subsequently shape their behavior in relation to those spatial cues. Locomotor play is also sometimes associated with

exploration, but it is found in fewer species than locomotor exploration. It provides a different type of information.

**Investigatory Behavior.** This term refers to various behavioral activities, such as interaction with the object being examined, manipulation of the object, investigation of a particular area (prolonged sniffing), etc. This is done through the mental representations an animal creates of the objects it examines. Learning the properties of these objects and their relationship to other elements in the environment takes place via perceptual exploration coupled with investigative responses. These two forms of activity allow the animal to enrich its existing representations of objects with their properties and attributes. Perceptual exploration makes it possible to replenish the existing representation of an object or area with information about its stimulatory properties. Manipulatory responses allow the animal to add information about the weight and structure of the object being explored. They also allow for the creation of contingencies between a given behavior and the environment. Both forms of information gathering are shaped by the animal’s ability to construct complex cognitive representations of objects. They are therefore a prerequisite for more advanced information seeking: knowledge seeking at the cognitive level.

An important new aspect at this level of information seeking is that the properties of an object become crucial to the regulation of the behavior in question. Complex novel stimuli (objects) become powerful incentives to begin exploratory and manipulative activities. There is also another dimension to novelty which involves not only relocation of a familiar object in space or the introduction or removal of a new object. Exploration may simply be triggered by a change in the object’s properties. Investigatory responses are induced in reaction to a change in a familiar environment (Pisula et al. 2019).

**Cognitive Curiosity.** This term covers seeking novelty and information at a cognitive level. Daniel Berlyne was probably the first to notice the close relationship between exploratory behaviors and cognitive activity (Berlyne 1962). He coined the term “knowledge-seeking behavior” and

emphasized the symbolic character of knowledge acquired in this manner. Berlyne attributed the highest level of complexity to the following basic types of activity: epistemic observation, consultation, and directed thinking. Within the integrative levels framework (Pisula 1998, 2009), epistemic observation must be categorized as a sophisticated form of perceptual exploration. Consultation, on the other hand, forms part of information seeking, as does directed thinking. This modification does run counter to Berlyne's intended classification, as he placed directed thinking at a privileged position in terms of behavior regulation. This modification, however, takes into account the integrative levels and the ecological approach (Gibson 1979) that stress the dependence of the meaning of a certain stimulus on the individual's perceptual abilities.

### Motivation to Explore

Research on the motivational mechanisms of exploration has been inhibited by the absence of a precise definition of these behaviors. Whether exhibited spontaneously or in response to (often quite intense) environmental stimulation, these behaviors have been analyzed collectively. Multiple studies have looked at forced (i.e., extrinsically motivated) exploration and spontaneous (intrinsically motivated) exploration (Renner 1990). There is no doubt that every behavior of an organism is closely related to the stimulation present in its environment. It is important, however, to determine which component plays the key part in a given situation. A comparative psychologist would naturally be more interested in intrinsically motivated exploration, as it reveals the complexity of an animal's psychological processes. However, for technical reasons, tests commonly used in laboratory experiments are usually designed to study forced exploration. Studies that successfully measure spontaneous exploration are much less common, although they are currently considered to be the most promising.

As early as 1958, M. Glanzer presented a comprehensive summary of studies on exploratory behaviors. His review included more than

70 research projects on the subject. The results of these studies yielded the following conclusions:

1. Places in which there are complex or multiple stimuli are explored more intensely than places without such properties.
2. The intensity of exploration drops rapidly with time spent by the animal in a given situation.
3. The intensity of exploration decreases with repeated experiences of a given situation.
4. Lack of exposure to an experimental condition or a prolonged time of waiting for a stimulus intensifies exploration.
5. An opportunity to engage in exploration is rewarding and, as such, can be used as reinforcement in the operant conditioning procedure.
6. A decrease in exploratory behavior in a familiar experimental condition is generalized onto similar situations, and the degree of similarity between those situations is a good predictor of exploration intensity.
7. To a large extent, exploration is independent of the amount of effort it requires. Thus, rats press levers offering various levels of resistance with a similar amount of effort, as long as this is an element of exploratory activity.
8. Exploration is not related to the ability to engage in motor activity in general: there are no differences in exploration between rats given access to a running wheel in their home cage and those deprived of such an opportunity.

In the summary of his article (which is exceptionally comprehensive given the early stage of research in that area), Glanzer lists key issues to be studied in the context of exploration:

1. Learning. What and how does an exploring animal learn? There is no question that it does in fact learn through exploration.
2. Exploratory drive. What is the nature of the exploratory drive? Is it similar to the hunger drive?
3. Stimuli controlling exploration. What attributes of stimulation arouse or inhibit

exploratory behavior? Are they stable or subject to change?

4. Fear of a novel stimulus. A high-intensity novel stimulus will not arouse stimulation but provoke escape or ceasing of all locomotor activity. What mechanisms determine the change in the function of a stimulus?

Research focused on the above issues has shaped our current understanding of exploratory behavior. There is not a single universally accepted definition of curiosity, but research on this phenomenon is dominated by three main traditions. The first and oldest builds on the drives theory (exploratory and boredom drives). The second is linked to the ideas of Hebb (1955), which draw on the hypothetical state of optimal arousal. The latest approach emphasizes the informative aspect of exploration.

The hypothetical drives of curiosity and boredom may be analyzed together, since, as noted by Russel (1983), they are compatible. The boredom drive hypothesis (Myers and Miller 1954) assumes that as the situation of monotonous stimulation persists, an organism generates drive tension. The curiosity drive hypothesis (Montgomery 1953) predicts that tension is generated as a result of the absence of access to varied stimulation. It can be easily demonstrated that these two concepts are reversible. The drive theory exerted a lasting influence on the psychological theories and therefore merits a more detailed analysis.

When analyzing theoretical concepts, it is vital to formulate predictions on the basis of a given model. Research hypotheses based on the above model would be as follows:

- With the passage of time and with no access to stimuli that could trigger a drive behavior, the threshold of sensitivity to these stimuli decreases, while the intensity of the triggered behavior increases.
- After a long time spent in an environment devoid of stimuli triggering drive behaviors, elements of the drive behavior chain will occur in the absence of the triggering stimulus (“releaser”) due to the accumulation of “drive energy.”

Analyses of the experimental data on exploratory behavior reveal no solid evidence in support of the drive theory. Birke and Archer (1983) obtained results that contradicted the first hypothesis and found that sensory deprivation does not always provoke an increase in exploration. Subsequent studies have shown that the increase in exploration following sensory deprivation is consistent with the expectations of the drive theory. The increase in the activity of rats subjected to sensory overload, however, suggests a more complex mechanism regulating exploration.

In summary, deprivation or sensory overload may lead both to an increase and to a drop in the intensity of exploratory behavior. This is probably due to the fact that there are other variables involved in the regulation of these behaviors, unaccounted for in the exploratory drive theory.

Another hypothesis arising out of the single-drive theory of exploration is that since various forms of this behavior are triggered by a common mechanism, they should be covariant. However, Barnett and Cowan (1976) published results demonstrating that the correlations between various forms of exploration are relatively weak. A theoretical analysis (Pisula 1998) also shows that different forms of exploration must be driven by different control mechanisms characterized by various levels of complexity and organization. Thus, despite the advantage of simplicity and apparent universality, the drive theory (of boredom or curiosity drive) does not explain exploratory motivation sufficiently well.

Since the early 1950s, the search for the mechanisms that control exploration gravitated towards systems based on maintaining an optimal level of nervous system arousal. Although the same concept was considered by multiple authors, it was presented in its most mature form by Hebb (1955). To mark its importance, the article was reprinted in Fowler’s (1965) collection of essays on exploration. Hebb opens his analysis of motivational processes by listing two central aspects of sensory experience: the cue function and the arousal function. He defines arousal as the most general drive and emphasizes its energizing aspect: “the drive is an energizer, but not a guide; an engine but not a steering gear” (Hebb 1955, p. 249).

The analysis of the relationship between cue effectiveness and cerebral cortex arousal prompted Hebb to propose the inverted “U” hypothesis, according to which there is an optimal level of cerebral cortex arousal for every activity. Thus, depending on arousal level, a given stimulation may improve the performance of a specific activity when the arousal level is low or deteriorate it when the level is too high.

This process is central to our understanding of motivation in higher animals and humans. An organism seeks to maintain the optimal level of arousal. Even though Hebb uses the term “drive,” his concept is in stark contrast to theories based on the classical drive theory. In the traditional approach (e.g., Lorenz), an organism is motivated to act when drive anxiety is reduced. According to Hebb, an intensification of drive anxiety may have the same effect. This difference has important consequences, including an impact on learning. In the classical drive theory, the positive rewarding value is assigned to those events that reduce the drive. In Hebb’s approach, it is ascribed to those that move the arousal level (through the stimulation they provoke) to its optimal value. Thus, the same response may be rewarded or punished depending on the state of the organism at the time of its occurrence. Exploration is undoubtedly a source of new stimulation and, as such, it increased arousal. Thus, according to Hebb’s theory, exploratory behavior occurs when the organism seeks to increase its arousal. This hypothesis laid the foundations for developing an area of research on exploratory behaviors that treated them as symptoms of a wider class of activities resulting from the need for stimulation.

The final conclusion is that there is a certain relationship between exploratory behavior, on the one hand, and the need for sensory stimulation driven by the Hebbian mechanism of optimal arousal, on the other. The relationship is positive, that is, individuals with a strong need for stimulation tend to explore more than those with a low need for stimulation, albeit by no means straightforward. While it must be taken into account in the theory of exploratory behaviors, it does not explain them. The results show that the mechanism described by Hebb does indeed play some

role in controlling exploration, but it is neither the only nor the most prominent factor in that process.

An alternative to the “drive” and “arousal” approaches to the factors underlying exploration was explored by researchers focusing on its information-seeking function. This function has two components: the informative (signal) value of stimulation and the content of the information warehouse (however understood) at the organism’s disposal. As indicated above, Glanzer (1958) proposed a system for analyzing exploration that must be regarded as one of the first theories explaining this class of behaviors. He was among the first authors to emphasize the role of information gathering in the regulation of these behaviors. Glanzer based his reasoning on the indisputably correct assumption that an organism is a system that processes information from the environment. This system requires a certain amount of information to be received in a given space of time. If the inflow of data is insufficient, it is actively increased through exploratory activity. If, on the other hand, the amount of incoming information is excessive, it is reduced by avoidance and freezing. Information needs are determined by earlier experience: an animal that experiences an inflow of a significant amount of information puts high demands on itself (raises its standards). Conversely, an animal kept in conditions of information scarcity sets itself low requirements in this respect. Though very neat, Glanzer’s theory has not gained many supporters due to problems with the operationalization of the variables studied, which resulted in conflicting empirical results (cf. Inglis 1983).

The search for a mechanism based on the informative content of stimulation resulting from exploratory behavior has developed towards analyzing the relationships between exploration and changes in stimulation. Novelty and complexity of stimulation are both psychological functions of the stimulus itself and of the state of the organism. The same stimulus can thus be more or less novel/complex, depending on the preexisting experience-based expectations of the organism. For the same reason, objectively different stimuli may have similar subjective values. This approach to the attributes of stimulation in the context of

exploratory behavior has become a constant feature in the analysis of animal behavior when encountering a novel stimulus. The idea that the organization of animal and human behavior may, to a large extent, be based on the comparisons between what is expected with what is actually observed is not new. One of the first authors to examine this mechanism was Salzen (1970, 1991).

In his analysis, Salzen pointed out that the mechanism underlying exploration is based on a comparison of the neural environmental model that is constructed as the organism gathers experience with the present stimulation from that environment. The discrepancy between the two is what prompts the animal to engage in actions aimed at reducing and ultimately eliminating that discrepancy. A small discrepancy triggers exploration, while a significant one triggers a flight response. The discrepancy between the observed stimulus situation and its neural representation is often cited in the attempts to explain the motivational basis of behavior. Archer (1976) developed an essentially analogous theory of agonistic behavior regulation. The appearance of another animal is a novel stimulus, which results in a discrepancy between the current neural model and the sensory input of the organism. A small discrepancy leads to aggression, while a bigger one to flight. Both categories of behavior serve to reduce this discrepancy.

The concept of motivation for exploratory behavior that took into account the mechanism of comparing the representation of the stimulus situation and the actual input was put forward by Inglis (1983, 2000). His model is also the most advanced – making use of the ideas derived from cognitive psychology. In short, it consists of the following hypotheses:

- Animals tend to form representations of their surroundings.
- These representations modify their behavior by generating expectations towards the current stimulation received from the environment.
- Attention processes are focused on stimulation, which differs from these expectations. They result from the mechanism comparing

the stimulation from and the representation of the environment.

- The intensity of biological needs modifies expectations towards stimulation by affecting the comparator mechanism.
- The strength of response to a stimulus is the function of the activity of the comparator mechanism triggered by this stimulus.
- The efficiency of assimilation of new stimulation and its integration into the existing representation depends on the ability to accommodate a stimulation deviating from the model and on the complexity of the existing representation.
- Whether the animal engages in exploring new stimulation or escapes depends on the intensity of the comparator mechanism response related to the particular efficiency of stimulation assimilation at a given point in time.

The mechanism operates as follows: an organism receives a specific input from the environment. The filtering mechanism (operating as part of the analyzer) isolates a set of potentially significant stimuli through automatic stimulation processing. This set is analyzed further by a hypothetical comparator mechanism. As a result of the analysis, appropriate behavior is triggered. If the expectations and the stimulus match, this triggers behavior aimed at satisfying a given biological need. If there are discrepancies, the orienting reflex is triggered first, followed by exploration (or flight) aimed at reducing the disparity.

In his comprehensive article, Inglis (1983) expressed his hope that the above theoretical idea would prompt extensive empirical research. This wish, however, has never materialized for a number of reasons. One problem is the complexity of this model, which makes it difficult to use as a basis for predicting the behavior of a given animal in a specific situation. It is even more difficult to determine what findings would be “prohibited” by this theory, that is, their occurrence would effectively be tantamount to a refutation. Furthermore, all theories based on the concept of discrepancy between the expected and the observed states have a common

methodological problem: discrepancy cannot be quantified with any precision. When discussing theoretical assumptions, terms such as “large” or “small” discrepancy make sense. Nevertheless, when researchers attempted to verify the presence of the theoretical processes empirically, the mounting difficulties often forced them to abandon their projects altogether. However, this theoretical framework for describing the relationship between the organism and its environment undoubtedly provides a tool for formulating hypotheses regarding the ways of coping with environmental change.

Berlyne's theory (1962) was a serious attempt at a synthesis. Berlyne analyzed two basic concepts related to the motivational mechanisms of exploratory behavior: arousal (interpreted as drive) and arousal potential. Arousal potential is a variable describing the relationship between the expectations regarding the stimulation properties of a given environment and the actual properties of that environment. Any departure from these expectations (although Berlyne did not use such a term himself), in any direction, results in increased arousal (curiosity drive). The relationship between arousal and arousal potential is therefore a U-shaped curve (Fig. 1).

Arousal potential is influenced by affective stimuli, strong stimuli, and internal stimuli. Their effect is modified by the following cognitive variables: novelty, complexity, and uncertainty. The

**Exploratory Behavior, Fig. 1** D. Berlyne model of the relationship between arousal potential and the attractiveness of stimulation and arousal. (Reprinted by permission)

exploratory behavior motivation theory proposed by Berlyne is probably the most frequently quoted one. In hindsight, Berlyne's theoretical model was an important contribution to the understanding of the mechanisms regulating exploratory behavior. While its predictive value is not particularly impressive, Berlyne's theory is important owing to the synthesis of elements derived from many different theoretical traditions: elements based on the curiosity/boredom drive, optimal arousal, and concepts derived from information theories. Creating such a theory is no easy task, and Berlyne took the first step in the right direction.

Ethologists were critical of the psychologists' efforts. In a monograph summarizing the achievements of ethology, Konrad Lorenz (1982) formulated some important hypotheses for the issues discussed here. First, he pointed out that exploratory behaviors differed from other behavioral classes: their uniqueness was due to the fact that an animal exploring an object employs a variety of locomotor patterns belonging to multiple drive categories and switches between them easily. When exploring a completely novel object, an animal may approach it as it would a dangerous enemy, attack it as a potential victim, try biting or carrying it, etc. Lorenz believed that exploration performed in this manner is objective in the literal sense of the word. The object becomes familiar in many respects, and the knowledge of its properties is stored for potential future use. As regards the motivational mechanisms, Lorenz emphasized their distinctiveness. This hypothesis is supported by the important finding that exploration comes to an end immediately when arousal of another kind occurs, for example, fear, pain, or hunger. Exploration occurs only in a field devoid of tension.

The foundations for modern ethological theory were laid by Buchholz and Persch (1994). These authors make use of the fundamental concepts of ethology. Stimulation received by an organism may be divided into two basic kinds: specific stimulation, that is, stimulation “targeted” at a specific release mechanism (RM), and nonspecific stimulation. The concept of the release mechanism was put forward by Tinbergen and Lorenz (1938). Lorenz (1982) presented a comprehensive analysis of this concept. According to Lorenz, the

release mechanism is a functional unit that belongs to afferent processes. It was originally referred to as the innate release mechanism (IRM) (Lorenz 1982; Tinbergen and Lorenz 1938). This term denotes a hypothetical mechanism enabling the animal to recognize biologically significant stimuli without prior learning. Recognition, in turn, triggers action readiness. This state, where stimulation is still being received, may transform into the arousal of the motoric coordination center (MCC), which controls a given behavior. Stimuli recognized by the release mechanism for exploration are frequently recognized by the release mechanism for flight. The action readiness system linked with exploration is inhibited by the flight readiness system. This results in behaviors that are typical of conflicts between drives, such as alternating exploration and flight (ambivalence) and displacement behavior (Tinbergen 1951). Which system becomes dominant in a given situation depends to a large extent on the modifying effect of memory, the influence of nonspecific stimulation and internal stimuli. The dominance of action readiness leads to the activation of appropriate motoric coordination centers and the launch of the exploration program.

It would be difficult to compare a theory based on an ethological approach with strictly psychological models. The differences in the conceptual frameworks used to describe the phenomena are too vast. The ethological theory, however, is undoubtedly an attempt at integrating exploration (while maintaining its distinctiveness) into the overall system of behavior regulation. This is where a clear advantage of this model of exploration lies. On the other hand, it would be exceedingly difficult to formulate verifiable hypotheses based on this theory. Detailed hypotheses could be proposed only if concepts such as “memory storage” or “external factors” were defined using psychological concepts, that is, if there was a description available of how these elements affect action readiness and the release mechanism. These improvements would bring the model closer to information-based theories.

Action readiness concept is compatible with the non-specific arousal of the central nervous

system (CNS), a concept employed by Berlyne (1962), and Hebb (1955). The ethological approach to exploratory behaviors thereby complements the psychological analysis with an important and comprehensive perspective but does not exhaust the potential scope of that analysis. There is still uncharted ground between the two approaches waiting to be illuminated by means of an integrated theory of exploratory behaviors.

Regardless of the internal regulatory mechanisms that determine the exact form of exploratory behaviors, there is no doubt that the novelty of a stimulus functions as a critical reinforcement (reward).

## External Fertilization

Megha Das, Nitesh Kumar Mishra and Sanjeev Kumar Yadav  
Department of Zoology, Institute of Science,  
Banaras Hindu University, Varanasi, UP, India

### Definition

**External fertilization** or “the ancestor of internal modes of reproduction” is generally a widespread reproductive approach of aquatic animals including both invertebrates (coelenterates, annelids, mollusks, echinoderms) and vertebrates (fishes and amphibians) in which male and female gametes are released into the aquatic environments and fertilization occurs outside of the body (Giese and Kanatani 1987; Jigersten 1972; Parker 1984; Wray 1995; Rouse and Fitzhugh 1994).

### Introduction

Fertilization is the combination of haploid male and female gametes forming diploid zygote to begin a new life. Fertilization may occur inside the body of a female (internal fertilization) or outside the internal milieu (external fertilization). Our focused area is external fertilization which usually ensues in water or a humid area to ease the travels of sperms to the egg. Females and males spawn freely into the environment which might be triggered by various factors such as water temperature or the length of daylight. The trigger for spawning causes the egg and sperm to be in a small area, enhancing the likelihood of fertilization. This is not only the environmental triggers that signals and controls the spawning process; other male and female physiological components and phenomena also regulate the

entire process. Due to the presence of different types of species in the same environment with same breeding season and having same kind of environmental triggers, they face various challenges such as to address the right chance of contact of the gametes of the same species as well as on prevention of getting fertilized by sperms of another species. Thus, to overcome these encounters, these organisms have evolved several mechanisms which we are discussing below.

- (a) **Environment:** Gamete concentration is the primary factor for either a male or a female spawner which regulates the probability of external fertilization. Several field experiments have documented that in an aquatic milieu gamete can diffuse and rapidly convert diluted resulting in declined fertilized egg ratio. This depends on various aquatic environmental situations such as high-wave-intensity shores, increasing water flow, or increasing water velocity. These environmental factors are responsible for the very fast diffusion of gametes that sometimes males set apart greater than 10 cm up current from a female have deposited her eggs which in turn increase the rate of mixing. This situation come up with bigger gamete clouds, more gamete diffusion and plunging the probability of gamete contacts which abridged the fertilization achievement (Pennington 1985; Denny and Shibata 1989; Levitan et al. 1992; Petersen et al. 1992).
- (b) **Population:** At the populational viewpoint, gamete concentration and the probability of sperm-egg meetings are also matriculated by following four factors, i.e., the distance between folks, richness of folks, rate of gamete release, and timing of gamete release. These four factors have strong impact on the local concentration of gametes followed by fertilization success. The distribution and richness of concurrent spawners are determined by the group behaviors such as accumulation and synchronization of spawning. Various experimental studies documented previously that fertilization declines to about 20% at 1 m and about 1% at 10 m (Pennington 1985; Yund 1990; Levitan et al. 1991; Yund and McCartney 1994; Levitan and Young 1995). Spawning in natural environment also shows that female spawning occurs from the distance of several meters from a male, possess very low levels of fertilization. Thus, fertilization success depends on the male and female richness which ensures the female distance from a spawning male.
- (c) **Individual's behavior:** Individuals also can have impact on the gamete dispersal in the aquatic environment. Individual of the population can generate fluctuations in the frequency and timing of gamete release, spawning behavior, and the expanse of energy investment during reproduction. The dispersal of gametes in the environment depends on the rate of gamete ejection from the gonopore. A high spawning rate increases the gamete concentration (Denny and Shibata 1989) but decreases the spatial extent of the gamete cloud. A high spawning rate again allied with high spawning synchrony, close male-female pairing, and intense sperm race.
- (d) **Production of gametes:** These organisms harvest massive quantity of gametes. The occurrence of the fertilized eggs and emerging young in the water provides prospects for predation, ensuing in a forfeiture of offspring. Hence, millions of eggs must be produced by folks. The offspring produced over this way must be developed rapidly. The endurance rate of eggs produced over broadcast spawning is truncated.
- (e) **Sexual selection:** It seems like sexual selection may not appear to arise during external fertilization, but it can by few ways. Two types of external fertilizers are classified, i.e., nest builders and broadcast spawners. Female nest builders mainly focus on the location finding to lay her eggs. A female mainly picks a nest adjacent to the male she desires to fertilize her eggs, which is not guaranteed that any of the eggs will be fertilized by the favored male. Due to the randomness of releasing gametes, broadcast spawners possess very feeble assortment (Robalo et al.

2012). Alonzo et al. (2016) performed an experiment to investigate the outcome of female choice on external fertilization; an in vitro sperm race experiment was done from where they found declined importance of sperm amount but amplified the importance of the sperm velocity resulting in changed sperm race outcome. Interestingly they also found that the ovarian fluid possesses impacts on the increased paternity for the favored male as they release fewer and faster sperm. The achievement of an external fertilization thus relies on the aptitude of a male's sperm to outcompete other sperm that is beholding to fertilize the same egg which is mostly governed by sperm chemotaxis, i.e., the chemical signals which gives sperm the capacity to navigate an egg and hence possess vast aids to reproductive success (Hussain et al. 2016).

- (f) **Species-specific sperm attraction:** Species-specific sperm attraction has been reported in all species which encounters external fertilization, such as cnidarians, mollusks, echinoderms, fishes, amphibians, and urochordates (Miller 1985). As we discussed above about chemotaxis, i.e., a chemical gradient secreted by the eggs, it basically attracts sperms toward eggs of their own species. After reaching maturity, these oocytes release the chemotactic factor, governs not only the type of sperm they appeal but also the time of sperm attraction. This chemotactic factor creates a gradient surrounding the eggs. This species-specific chemotactic factors recognizes and binds to the specific receptor situated at the outer surface of the sperm head or acrosomal sac. The mechanism of chemotaxis is diverse among species, and chemotactic molecules are different even in closely inter-related species. For example, the gonadal pH of *Arabica punctulata* is kept low (about pH 7.2) by the high concentrations of CO<sub>2</sub>, and thus the sperm cells inside testes show no movement and motility is acquired only after spawning (Eisenbach 2004). Once sperms are spawned into seawater, the pH raise to about 7.6, resulting in the stimulation of the dynein

ATPase which splits ATP, providing the energy for the flagella to wave, and thus sperms commence vigorous swimming (Christen et al. 1983). The sperm movement in *Arabica punctulata* also needs the right direction to swim, and this direction is governed by a small chemotactic peptide, i.e., Resact, a 14 amino acid peptide, which diffuses radially from the outer jelly layer of the egg and makes a gradient (Ward et al. 1985). This sea urchin-specific chemotactic peptide can only be recognized and bind with its specific receptor situated on the sperm head which then gives the direction toward the gradient and finally allows to attach with egg (Kirkman-Brown et al. 2003).

- (g) **Success of fertilization:** In external reproduction, the close proximity of egg and sperm doesn't occur because animals always scatter their gametes through a body of water. This scattering reduces the possibility to the meeting of sperms and eggs resulting in many of the sperms and eggs dying before attaining fertilization. Hence, this low achievement rate of external fertilization puts aquatic-free spawning animals at a reproductive drawbacks compared to internal fertilization.

## Examples of External Fertilization

### Invertebrates

Most invertebrates are benthic sessile animals, maintaining their progeny by external fertilization that depends on ambient water motion which gives the proper atmosphere to meet the sperm and eggs together. Other invertebrates like the sea urchin also fertilize externally in the restricted to shallow burrows on bare shores where turbulent flows aid in gamete transports (Costa et al. 2016). The efficiency of fertilization in invertebrates is primarily governed by the spawning properties (i.e., gamete quality, gamete proximity, and spawning time) and its hydrodynamic environments (i.e., turbulence, water current, water velocity, etc.) which influence the rate of water mixing in the gamete cloud (Thomas et al. 2013). For example, increased turbulence in the water dilute

sperm and egg due to rapid mixing of water resulting in lower probability to fertilize (Costa et al. 2016). Sessile adult invertebrates prefer a synchronized production and release of gametes in the water column which helps increasing fertilization rates due to lack of share mobility of these organisms (Mercier and Hamel 2010). Before synchronized release of gametes, these animals also choose a place where all future survival factors such as the presence of food, resources, and favorable environmental conditions and the lack of predators is present for of the next generation, and then they go for gamete release (Forrest and Miller-Rushing 2010). To enhance the fertilization probability, they also rely on turbulent mixing and sperm mobility (Costa et al. 2016). Before a mass reproductive event, i.e., when multiple females are producing and releasing eggs in the water body, they accomplish predator satiation (Kelly and Sork 2002). The Great Barrier Reef is known as the place for “mass spawning” where a mass reproductive event of almost 130 species occur, starting from the week after the full moon in October and continues from dusk to midnight (Harrison et al. 1984; Willis et al. 1985). In some cases, fertilization can also ensue on the surface of a spawning animal and when the animals are in the turbulent wake (Thomas et al. 2013). Although, this fertilization on the surface of spawning animal does not follow traditional short-term external fertilization process due to the possibility of gametes being engaged on the surface of an animal for a prolonged time period (Marshall 2002). With the purpose of release an egg or sperm over time, gamete clusters are formed that drift in the water column which gives a variation in fertilization of the same invertebrate by changing locations and time differences (Thomas 1994; Thomas et al. 2013).

### Vertebrates

- **Amphibians:** External fertilization in vertebrates started till 300 million years ago. From Anura (Browne et al. 2015) to Caudata. Among the amphibians, anurans lack tail like frog and toad (Browne et al. 2015; Arak 1983). Due to the large, easy to manipulate eggs, fast developmental rate, high fecundity rate, no

parental involvement, and capability of external fertilization, anurans are used to be the common model organisms. In the mating season, males approach females by producing species-specific mating call from the “calling station,” i.e., near the lake or pond, where they gather at the mating season before approaching. Females firstly judge those approaches coming from different males and the move toward that male whom she chooses, and this is how the anurans ensure their sexual selection. The selection also depends on the body size of the male which has been supported by another observation that sperm number is associated with testes size which in turn depends on the body size (Browne et al. 2015; Bruning et al. 2010). For example, the larger the body size, the larger the testis size with increased number of sperm. During copulation, male anuran hops on the back of the female and moves toward the chosen spot where they simultaneously release their gametes. Fertilization is not necessarily done with the hopped male; other males of that area can also release their sperm to attempt fertilization. In this kind of situation sperm competition increase through agonistic behavior and spawning in groups because anuran sperms have high longevity and osmotic tolerance (Browne et al. 2015). Sometimes females don’t want to fertilize her eggs by the hopping male, and in that situation, she waits until the male leaves her back and moves to another place (Zhao et al. 2016). When preferable pairing occurs, the pair tries to release their gametes in close proximity, so that sperms get the best chance to enter the gel layer of the eggs followed by successful fertilization. If the gametes are not in enough proximity males occasionally release their sperm into oocyte containing foam nests to go precisely to the gel coat of the oocyte to release their sperm (Browne et al. 2015). Males target a female who is about to spawn along with releases their sperm anywhere he finds unfertilized eggs over the passage of a breeding season while females can only release their eggs once per breeding season (Zhao et al. 2016).

*Cryptobranchidae* (giant salamanders) Sirenidae, and Hynobiidae are the amphibians of the order Caudata that have tails (Browne et al. 2015). These external fertilizers group animals also possess almost the same kind of factors and processes to achieve their successful fertilization. Here, the males become protective toward the eggs after copulation and starts to hover over the eggs to reduce the sperm competition. In some cases, males become overprotective toward the eggs to ensure paternal success that they even latch onto the female during her egg laying (Houck and Arnold 2003).

- **Fish:** All fishes are the external fertilizers, among the every common examples are salmon, cod, trout, and char. The fertilization protocol is common to all other external fertilizers, i.e., release of male and female gametes into the water which diffuses and meets to form a new life (Stoltz and Neff 2006). Like in amphibians, the success of an external fertilization in fish also depends on the lower water velocity or turbulence along with closer proximity between gametes which in turn increases the chance of penetration of the sperms into the gel layer of eggs, leading to a successful fertilization (Browne et al. 2015). Sometimes the timing of gamete release also can be an important factor, i.e., suppose the male release his sperm too early, then sperm got diluted and die before the reach to egg and thus it gives the higher chance to other sperms from other fishes to fertilize the eggs. Same thing happens if they lost the proximity. Also, higher sperm velocity and larger sperm amount increase the probabilities of fertilization (Stoltz and Neff 2006). There are examples where males build habitats to monopolize females and upsurge his paternal success (Browne et al. 2015). Mostly fishes are iteroparous, and spawn more than once, but exceptions are always in the nature such as semelparous fishes, i.e., which spawn once before death. Within iteroparous fishes, they show no parental care (Murua 2014). The sperm motility depends on the environmental conditions. For example, a salmon sperm motility depends on the decrease of potassium in fresh water, or a

cyprinid fish's sperm motility depends on the decrease in osmolality after spawning in fresh water (Dzyuba and Cosson 2014).

## Conclusion

As discussed above, the success of external fertilization depends maximally on the environmental factors such as pH of water, water turbulence, water velocity, osmotic pressure, mineral level, presence of predators, etc. Some biological factors related to parents like gamete longevity, gamete proximity, timing of gamete release, etc. also controls the probability of external fertilization. Although a successful external fertilization faces several environmental and biological hindrances, this is still a strong natural fertilization process where a large number of offspring is produces with low parental energy investment. Due to the lower probability to be fertilized, both male and female produces large number of gametes. In contrast, external fertilization shows less survival rate of offspring due to lack of parental care as well as higher risk of being predated by other species along with their own parents. Still external fertilization is an evolutionary selected fertilization procedure for a large amount of aquatic species due to its sexual selection strategies, sexual dimorphism, limitation to become overpopulated, and higher probability of genetic variations.

## Extinction in Learning

Prescilla John

United States Army, New York, NY, USA

The term extinction was coined by Russian physiologist Ivan Pavlov who became the first to employ a classical conditioning procedure, also known as a Pavlovian conditioning learning paradigm, through his study of dogs (Dickinson and Mackintosh 1978; Domjan 2010; Pavlov 1927). Extinction can either refer to an associative learning procedure where the reinforcer is removed or a decline in responding as a result of an absent reinforcer (Pavlov 1927). In order to conceptualize extinction, it is important to understand learning processes such as classical conditioning and instrumental conditioning, which both utilize associative learning procedures. During a classical conditioning procedure, a biologically relevant or unconditioned stimulus (US) is paired with a previously neutral or conditioned stimulus

(CS) to produce a conditioned response (CR). In classical conditioning, the innate or unconditioned response (UR) to a biologically significant stimulus becomes evoked by the pairing of the conditioned or previously neutral stimulus with the unconditioned stimulus. When the unconditioned stimulus is presented in the absence of the conditioned stimulus, the conditioned response is expected to diminish, a process known as extinction. In other words, extinction refers to the gradual decrease in a response due to the removal of a conditioned stimulus.

While classical conditioning refers to how an organism adapts to uncontrollable changes in their environment, instrumental or operant conditioning is a type of learning in which stimuli encountered are a result of an organism's behavior (Bouton and Swartzentruber 1991; Pavlov 1927). In instrumental learning, the organism's behavior is instrumental in producing a particular outcome, which either serves as a reinforcer or a punishment for such behavior in the future. Extinction in learning can occur subsequent to the learning of both classically and instrumentally conditioned behaviors. However, as noted by Pavlov (1927), extinction only produces a temporary loss of conditioned responses; following a passage of time, originally learned associations are likely to recover.

## Extinction in Classical Conditioning

Classical conditioning is a form of learning that allows for human and nonhuman animals to learn about relations between one event and another through the pairing of a biologically relevant stimulus with a biologically neutral stimulus (Pavlov 1927). During a classical conditioning procedure, the experimenter is expected to create a relationship between the stimulus and the reinforcer through repeated pairings of the two. This is known as the stimulus-reinforcer contingency, where the conditioned stimulus (CS) is paired with an unconditioned stimulus (US). In Pavlov's famous experiments with dogs, he paired food, which served as the biologically significant stimulus, with a previously neutral stimulus (e.g., the

sound of a metronome) to create a conditioned response (e.g., salivation). Pavlov noticed that the dog learned to salivate at the sound. However, the response became weakened when the stimulus-reinforcer contingency was removed; that is, when the bell was no longer paired with food, a significant decrease in the conditioned response occurred over time.

When the unconditioned stimulus or reinforcer is omitted and the conditioned stimulus is consistently presented in isolation, this is referred to as extinction (Pavlov 1927). While it may appear that the loss of the conditioned behavior observed in extinction may imply forgetting, it is important to note that it does not equate to forgetting or unlearning. Extinction is different from memory loss in that it is an active process that occurs due to the absence of the unconditioned stimulus. It is also referred to as an active inhibitory process because the conditioned response reemerges following extinction when tested after a prolonged period of time has elapsed; this is a phenomenon that occurs as a result of exposure to the conditioned stimulus, without any additional training. The ability for the previously extinguished conditioned stimulus to elicit a conditioned response is a strong indication that the original CS-US association still remains post extinction.

## Extinction in Instrumental Conditioning

While studying animal intelligence, Edward Lee Thorndike (1911) serendipitously began some of the early laboratory and theoretical analyses of instrumental conditioning (Bouton and Swartzentruber 1991). He was interested in understanding if animals possessed human intellectual capacities and to what magnitude. He studied this through the use of a puzzle box in which a hungry animal (e.g., cat, dog, or chicken) was placed in the box and had to determine how to get out of the box in order to obtain food. Each box he created required different responses to get out; some were more complex than that of others. While one box required the pulling of a ring, another box required a lever to be pushed. Although the animals took a while to

learn the associations, with more exposure, their latencies to get out of the box became much shorter. Thorndike believed that as the association between being in the box and the escape response became stronger, the hungry animal learned which behaviors led to favorable outcomes much quicker. He interpreted his findings as a stimulus response form of learning, which simply put means that a stimulus or cue is directly associated with an outcome. This is also referred to as an instrumentally conditioned response. In instrumental conditioning, extinction occurs when the behavior that was previously reinforced no longer produces reinforcing outcomes. In the experiment described above, if the hungry animals were to learn that food was no longer associated with escape, their stimulus response association would weaken. This would serve as an example of extinction in instrumental conditioning.

## Recovery of Responding After Extinction

Recovery of responding following extinction has been demonstrated in various experiments (Hermans et al. 2005; Leung et al. 2007; Lovibond et al. 2008; Norrholm et al. 2006). Following successful extinction, classically learned responses have a tendency to recover. Several studies have shown that conditioned fear is likely to return following the passage of time, a change in context or an aversive event. The way in which this recovery of responding occurs can be classified into several categories such as spontaneous recovery, renewal, or reinstatement. Recovery of responding following extinction demonstrates that extinction does not lead to unlearning and can be explained by the Rescorla-Wagner (1972) model of learning. This model suggests that the strength of the conditioned response is dependent on the strength of the CS-US association. According to the Rescorla-Wagner model, extinction results in the loss of the associative strength gained by the CS during conditioning. Various experimental findings on conditioning and extinction can be explained through the Rescorla-Wagner model (Bouton and Bolles 1979; Bouton and King 1983; Huff et al. 2009; Norrholm

et al. 2006; Zimmer-hart and Rescorla 1974). As a result, this model has been used as a reference point for subsequent learning theories (Siegel and Allan 1996). Overall, the recovery of responding following extinction supports Bouton's (1993) failure to retrieval theory which suggests that contextual and temporal cues play a role in the retrieval of extinction memories.

## Extinction and Spontaneous Recovery

Several studies have found that the time between extinction and testing impacts the long-term effectiveness of extinction in animals (Costanzi et al. 2011; Maren and Chang 2006; Myers and Carlezon 2010). While extinction produces a decline in conditioned behavior, this effect is weakened over time. When the previously extinguished response recovers following a rest period, this effect is called spontaneous recovery. Spontaneous recovery is a term that was originally identified by Ivan Pavlov. In a Pavlovian conditioning experiment by Rescorla (1997), rats in one group paired noise (CS) with food (US), while those in another group associated food (US) with light (CS). The CS in both groups, which served as a previously neutral stimulus, came to elicit conditioned responses more quickly over repeated presentations. Subsequently, 16 extinction trials occurred in both groups, followed by four test trials. In one group, testing occurred immediately, while there was an 8-day interval between extinction and testing in the other group. Although responding was suppressed for the group tested immediately after conditioning, responding recovered for the group tested 8 days after extinction. This recovery of responding is referred to as spontaneous recovery.

## Reinstatement

Recovery of responding can also be observed through the reintroduction of the CS-US relationship, where additional conditioning trials are administered post extinction, which primes the originally acquired association to recover

immediately. This phenomenon is referred to as reacquisition and tends to be more robust under fear conditioning (Bouton and Bolles 1979). The unconditioned stimulus is more likely to reinstate fear because it may serve as a retrieval cue for conditioning memories. Responses that have been successfully extinguished can recover following exposure to the unconditioned stimulus (Bouton and Bolles 1979; Rescorla and Heth 1975). In a study by Norrholm et al. (2006), participants were exposed to a fear conditioning paradigm where colored lights (CS) were paired with an air blast to their throat (US). Post 24 h of fear conditioning, participants received extinction trials. When the unexpected US was presented, participants demonstrated significant reinstatement of fear.

## Renewal

Another process known to produce a recovery of the originally learned association is renewal. Renewal provides evidence that conditioned responding is not context specific but can occur in contexts outside of the one in which conditioning originally occurred (Bouton 1993). When the extinguished conditioned stimulus is encountered outside of the extinction context, renewal of conditioned responding is observed. Studies have found that renewal of fear can be observed when an organism encounters the CS in a novel or familiar environment (Bouton 1993; Bouton and King 1983; Bouton and Swartzentruber 1991). For example, research on conditioned suppression found that fear of an extinguished CS can be affected by the excitatory strength of the context, but it is not context driven and can reemerge in any context (Hermans et al. 2005).

## The Importance of Extinction Training in Therapy

Cognitive behavioral therapies such as exposure therapy are a common treatment for psychological conditions like specific phobias, anxiety, and traumatic stress disorders (Barlow 2008; Craske et al. 2014). In exposure therapy, a person is exposed to

the feared stimulus or context without exposure to the US or the feared contingency. This exposure occurs either through in vivo (e.g., real life) or virtual reality (e.g., computerized CBT) exposure therapy. As previously mentioned, several animal and human learning studies have found that conditioned responses tend to recover following successful extinction treatment (Hermans et al. 2005). This effect has been observed in cognitive behavioral therapies such as exposure therapy, where conditioned fear has returned in up to 30–50% of individuals who have received successful treatment for an anxiety disorder, an effect also referred to as relapse in clinical practice (Choy et al. 2007; Craske and Rachman 1987). The return of fear following successful extinction serves as a manifestation that extinction creates an inhibitory memory which temporarily suppresses fear-related expressions until the passage of time, change in context, or reexposure to the US (Bouton 1993). Clinically speaking, this return of fear following extinction contributes to relapse when using exposure-based therapies for anxiety- and trauma-related conditions (Bruce et al. 2005).

While several studies have found evidence of fear recovery following extinction (Bouton and Bolles 1979; Hermans et al. 2005; Norrholm et al. 2006; Rescorla and Heth 1975), recent studies looking at the neural mechanisms of Pavlovian conditioning have since challenged this notion (Quirk et al. 2010). The neuroscience literature has found that extinction may erase some aspects of fear memory at a neural level, particularly in the amygdala (i.e., area of the brain involved in emotions), although fear may still be presented behaviorally. Research by Quirk et al. (2010) has found that altering the timing of extinction trials in both animals and humans has allowed for extinction training that has shown evidence of unlearning. These researchers have found that there are different neural circuits that mediate extinction of conditioned responses depending on the stage of development. In rats 24 days postweaning, extinction is dependent on the medial prefrontal cortex (mPFC), similarly to that of adult rats. However, in fear extinction at 17 days of age, the mPFC does not impact extinction. Rats that received extinction training at 17 days of age did not

exhibit a return of fear when tested in a different context (i.e., renewal) or following exposure to a stressor (i.e., reinstatement), like that of that of rats who received extinction training at 24 days of age. Therefore, these findings suggest that extinction-induced erasure is much more likely to occur in younger rats as opposed to older rats.

Recent findings suggest that the same effect is possible in human beings (Myers et al. 2006). It is possible for extinction training to update previously learned behaviors if it occurs within a specific timeframe, which would essentially reduce the risk for recovery of fear responses according to this research. Myers et al. (2006) found that when extinction training occurs immediately after fear conditioning, the fear memory is less likely to be consolidated. This implies that if extinction can be facilitated during the reconsolidation phase, fear associations can be reestablished as safe. Due to limitations in human causal learning, many studies have demonstrated that the time between extinction training impacts the effectiveness of extinction using animal models of fear (Corley et al. 2012; Maren and Chang 2006; Robbins 1990).

## Conclusion

Extinction is one of the most popular topics in the area of cognition and behavior theory (Domjan 2010). It offers transferable research that seeks to improve clinical practice based on findings from the laboratory (Bouton and Nelson 1998; Craske et al. 2014; Craske and Rachman 1987). Extinction has been very instrumental in providing implications for exposure therapy and relapse by looking at the factors that contribute to the persistence in responding, conditions that encourage a decline in responding, or the circumstances in which responses spontaneously recover (Craske et al. 2014). While extinction produces a diminished response to originally learned associations as a result of the removal of either a conditioned stimulus or reinforcer, following a rest period, the preexisting association returns. Other phenomena that lead to the return of fear include renewal or reinstatement. Renewal occurs when the CS-US

association is introduced in a new context (e.g., renewal), while exposing the organism to the CS post extinction in the absence of the US is likely to encourage reinstatement of responding. These phenomena serve as evidence that extinction does not lead to unlearning or forgetting. Although extinction was originally coined by Pavlov (1927), much of what we know about extinction today has been informed by research in the past few decades.

## Extra-Pair Copulation

Gisela Sobral

Departamento de Reprodução Animal, Faculdade de Medicina Veterinária e Zootecnia, Universidade de São Paulo, São Paulo, Brazil

## Synonyms

Cuckoldry; Cuckquean; Extra-pair copula; Extra-pair fertilization; Extra-pair mating; Extra-pair paternity; Infidelity; Sneaky matings

## Antonyms

In-pair copulation; Mate fidelity

## Definition

A paired individual opportunistically mates with an individual other than its social mate within pair bond.

## Evolutionary Context

According to Trivers (1972), there will be uneven investment in offspring related to the gender roles. At one end, is the sex that invests less in the offspring (the competitive end), and, at the opposite side, the sex that invests more (the choosier end). If both sexes invest a great deal in offspring, then both should be choosy. This high level of biparental care is unusual among animals, where female consistently holds a larger proportion of care for the young. Biparentalhood is, thus, more common among monogamous species, in which both parents form a pair bond and stay together for at least one breeding season in order to raise the young together, sharing the workload. Others form lifelong pairs (lifetime monogamy), sticking together for consecutive breeding seasons and successive broods or litters. Yet, monogamous species do not necessarily exhibit sexual fidelity.

## Extra Nipple

► [Supernumerary Nipple](#)

## Extractive Foraging Hypothesis

► [Technical Intelligence Hypothesis](#)

## Extra-Pair Copula

► [Extra-Pair Copulation](#)

Many pairs do not present exclusive sexual relationships, resulting in extra-pair copulation (EPC). Thus, the mating strategies of species are now separated into social monogamy, as defined by an exclusive living arrangement, and genetic monogamy, in which cohabitation is accompanied by exclusive parentage (see Lack 1968; Lukas and Clutton-Brock 2013).

EPC is expected to occur in both sexes depending on the reproductive strategy of the species. The large investment towards the raising of young increases the costs of extra-pair copulation, although it also renders increased benefits to the cuckold. In many species, the male pursuit of EPC is associated with its “gender role,” copulating with as many females as possible and investing little in offspring. Yet, he must also reduce the possibility of having his paternity stolen somehow. In turn, a female will pursue EPC to obtain benefits to her offspring and/or herself (Westneat and Stewart 2003). Female infidelity is the most important generator of sperm competition and, why not, generator of mate guarding in monogamous species.

Which benefits is the female looking for? Petrie and Kempenaers (1998) listed a few for birds, such as (i) seeking “good genes” (high genetic quality that will improve the survival or reproductive chances of their offspring); (ii) reduction of costs of mate loss (they will be able to find another partner quicker in the event of partner loss or death); or (iii) direct benefits (e.g., increased foraging opportunities, defense against predators and additional mates).

As for mammals, Solomon and Keane (2007) listed benefits of mating with multiple males that is similar to those for birds: (i) assurance of fertilization (nullifying effects of empty copulas); (ii) gaining material benefits (more paternal investment from males); (iii) better genes for offspring (probability of mating with high-quality males); (iv) mate compatibility; (v) increased genetic variability of offspring; (vi) prevention of harassment by males; or (vii) prevention of infanticide.

Many studies addressing mate guarding also address EPC, in that mate guarding and the pursuit of EPC are mutually exclusive (e.g., Lukas and Clutton-Brock 2013; Westneat and Stewart 2003).

For instance, highly synchronous estruses hinder the male ability to guard his partner and simultaneously seek for EPC. In some species, EPC overlaps the concept of group guard/monogamy (e.g., one male mating with or paired with multiple females as seen in the anemonefishes *Amphiprion akallopisos*, Fricke 1979). Yet, mate guarding is not always an effective mechanism to prevent extra-pair copulations. Some species with no obvious mate guarding maintain genetic monogamy. Many species described under mate guarding also have been reported to show EPC. However, Westneat et al. (1990) correlated monogamy, pair bonding and EPC, stating that, in order to EPC to occur, the bond needs to be long lasting. Thus, many examples should not be considered as EPC because they are related to brief associations between males and females. The maintenance of long lasting and equitable bonds is more common among birds and social mammals. Thus, EPC descriptions hereafter will focus on those two groups.

## Extra-Pair Copulation Examples

### Birds

Many birds are monogamous (around 90% of species), a mating system sometimes considered as an extended mate guarding. Therefore, extra-pair copulation has been described primarily for this group and later extended to others. Frequency of extra-pair paternity varies from zero in willow warblers *Phylloscopus trochilus* to more than half of the brood with extra-pair paternity in superb fairy-wrens *Malurus cyaneus*. For Westneat et al. (1990), who conducted an extensive review of EPC in birds, in communally breeding birds such as Acorn Woodpeckers *Melanerpes formicivorus*, matings with auxiliaries are not EPC because each male in the group has a long-term social association with the female. Consequently, they also do not consider polyandry as EPC if the female is normally part of a social unit that contains both her primary and secondary partners, such as dunnocks *Prunella modularis*. These authors also disregard lek-breeding birds, such as sage grouse *Centrocercus urophasianus* because they do not form pair bonds.

Males that present paternal care need to ensure paternity to reduce risks of expending parental investment on the offspring of other males. Communal species are more likely to present extra-pair copulation than solitary nesting ones. This scenario is even considered as the main disadvantage of colonial breeding. The bank swallow males (*Riparia riparia*) pursue extra-pair mates and spend more time at neighboring territories while females are incubating, although he guards her when she is sexually receptive.

Male birds have evolved an elaborate array of tactics to avoid cuckoldry, such as frequent mating and mate guarding. The regular copulation increases the amount of sperm introduced inside the female reproductive tract and, consequently, displaces any possible sperm from another male. Yet, frequent copulation also favors females as it depletes sperm storage and leads the male to exhaustion, reducing his chance to copulate with other females. Females will engage in EPC only if outside the view of her partner. Otherwise, paternal care will be sharply reduced if the proportion of offspring is sired extra-pairly. Thus, extra-pair copulas need to be unseen by the male mate so that he is misled as being the only father of the subsequent offspring and helps care for the young.

### Mammals

Monogamy is rare among mammals (3–9% of species, Lukas and Clutton-Brock 2013) and EPC has been widely studied in social species, such as primates and carnivores. In dwarf mongoose *Helogale parvula*, dominant males sired 75% of offspring; in African wild dogs *Lycaon pictus*, dominant males sired 80–90%; mountain gorillas *Gorilla beringei beringei*, dominants sired 75% of offspring; and in meerkats *Suricatta suricatta* dominant males sired around 86% of offspring. In some other highly social mammals, such as cetaceans, males use coercion to prevent the female from seeking EPC. Male bottlenose dolphins *Tursiops truncatus* sequester females and use force to deter her from extra-pair copulations and Humpback females *Megaptera novaengliae* resist consorting attempts.

Highly social mammals frequently present reproductive skew, in which a dominant pair monopolises reproduction. It is important to

emphasize that, in groups with highly skewed reproduction, EPC will not be as successful for the subordinate female as it would be for the subordinate male, as subordinate females will fail in their reproductive attempts. Subordinates will fail to conceive, reabsorb their embryos, or will lose their offspring to infanticidal resident/dominant females. In alpine marmots *Marmota marmota*, resident males have been cuckolded by their own subordinate males, satellite males and neighboring families. Subordinate females, on the other hand, did not succeed in many attempts. Conversely, a subordinate male may copulate with high-ranking females of his own group when the dominant male is occupied, or rove to neighboring families and copulate with the local dominant female. Although motivations vary among the species, one feature seems to be underlying: the genetic relatedness between social mates, with dominant females using EPC as a strategy to avoid the negative effects of inbreeding. Sometimes, the male meerkat that rose to dominance within a meerkat group is related to the dominant female (sons or nephews). Hence, the extra-pair males are no more distantly related than the social mate, but they are more heterozygous (Young et al. 2007). However, according Westneat et al. (1990), these examples may not constitute true EPC because females live in social groups where both the primary and secondary partners live together.

Regardless, EPC provides many benefits. For instance, multiple-paternity in the European badger *Meles meles* provides fitness advantages such as fertilization assurance, reduced harassment, decreased infanticide, genetic benefits by promoting sperm competition, increased litter genetic diversity, reduced genetic incompatibilities, compensation for poor-quality mates, and obtainment of good genes. Similarly, many primate species uses multiple matings to generate paternity confusion and entrust as many males as possible in the care of the young and prevent infanticide. By mating with potential invaders, these females might reduce risks of future infanticide, and encourage paternity confusion, as suggested for Old World primates, long-tailed macaques *Macaca fascicularis* and Hanuman langurs *Semnopithecus entellus*, but also New World

primates, such as howler monkeys. In red howler monkeys *Alouatta seniculus*, females that indulged in EPC had experienced infanticide previously (Agoramoorthy and Hsu 2000). For other species, such as rodents, there is evidence that multiple copulation and, therefore, possibly extra-pair copulation, provides the female with extra set of nutrients by the absorption of unused sperm. These motivations are in tune with those observed in birds (see above).

EPC in humans are particularly interesting. In human lineage, males seek high partner variety due to their “gender role”. As a counterstrategy, females present what is called “concealed ovulation” and it is suggested that this evolved to obtain a high quality sire without the detection by both EPC and primary partners (Benshoof and Thornhill 1979). Yet, women are not good themselves at detecting their own fertility so that they will cryptically pursue EPC. Humans are particularly susceptible to the negative effects of cuckoldry as parental investment failure is measured in years and some women have only one child throughout her entire life. Sometimes EPC has complex social consequences in Western cultures, such as diminished virility (for males) or decreased femininity (for females) and dwindled overall social reputation, decreasing his or her status. Conversely, for some cultures, the concept of “EPC” is meaningless as all men within a village help care for the babies (e.g., Bari people, in Venezuela, Hrdy 2001). For some other cultures, gender roles are interchangeable (e.g., African Aka tribe). However, whilst men can pursue other partners if he is cuckolded, the costs for a woman are lower as genetic cuckoldry will never happen to her: she will always be the mother of her child, regardless of the strategy of her culture or her partner’s unfaithfulness for those cultures in which it matters.

## Conclusions

Among animals, the female usually holds the large proportion of care for the young. Yet, in pair bonding species, biparental care is high and

both parents invest a great deal in the offspring. Biparentalhood is, thus, more common among monogamous species. Conversely, the formation of pair bonds yielded a breach for extra-pair copulation (EPC). EPC is common among birds, in which the majority of species are monogamous, and particularly common among carnivores and primates groups in mammals. EPC motivation is similar for birds and mammals, namely, fertilization assurance, reduced harassment, decreased infanticide, genetic benefits, by promoting sperm competition, increased litter genetic diversity, reduced genetic incompatibilities, compensation for poor-quality mates, obtainment of good genes, and pursuit of high partner variety. Both sexes will benefit or suffer from EPC advantages and costs depending on the reproductive strategy of the species and on the mating tactics of each sex.

Department of Computer Science, University of  
Warwick, Coventry, UK

### Introduction

Face-selective neurons were discovered in the inferior temporal visual cortex by Perrett et al. (1982), in the amygdala by Sanghera, Rolls, and Roper-Hall (Sanghera et al. 1979; Rolls 2011) and Leonard et al. (1985), and in the orbitofrontal cortex by Rolls et al. (2006). These neurons respond 2–20 times more to the best face compared to the best nonface, and different brain regions provide the basis for face recognition and for emotional responses to faces. These neurons are described here.

## Neuronal Responses to Faces in Different Temporal Lobe Cortex Visual Areas

Visual pathways project by a number of cortico-cortical stages from the primary visual cortex until they reach the temporal lobe visual cortical areas in which some neurons that respond selectively to faces are found (Perrett et al. 1982; Rolls 2007, 2011, 2012, 2016a). The inferior temporal visual cortex, area TE, is divided on the basis of cytoarchitecture, myeloarchitecture, and afferent input into areas TEa, TEm, TE3, TE2, and TE1. In addition, there is a set of different areas in the cortex in the superior temporal sulcus (Seltzer and Pandya 1978; Baylis et al. 1987) (see Fig. 1). Of these latter areas, TPO receives inputs from temporal, parietal, and occipital cortex; PGa and IPa from parietal and temporal cortex; and TS and TAa primarily from auditory areas.

Considerable specialization of function was found in recordings made from more than 2600 neurons in these architectonically defined areas (Baylis et al. 1987). Areas TPO, PGa, and IPa are multimodal, with neurons that respond to visual, auditory and/or somatosensory inputs (though not typically with corresponding bimodal auditory and visual responses (Sliwa et al. 2016)); the inferior temporal gyrus and adjacent areas (TE3, TE2, TE1, TEa, and TEm) are primarily unimodal visual areas; areas in the cortex in the anterior and dorsal

### Face Processing in Different Brain Areas and Face Recognition,

**Fig. 1** Lateral view of the macaque brain (*left*) and coronal section (*right*) showing the different architectonic areas (e.g., TEm, TPO) in and bordering the anterior part of the superior temporal sulcus (STS) of the macaque (see text; after Seltzer and Pandya 1978)

part of the superior temporal sulcus (e.g., TPO, IPa, and IPg) have neurons specialized for the analysis of moving visual stimuli; neurons responsive primarily to faces are found more frequently in areas TPO, TEa, and TEm, where they comprise approximately 20% of the visual neurons responsive to stationary stimuli, in contrast to the other temporal cortical areas in which they comprise 4–10%. Moreover, neurons with responses related to facial expression, movement, and gesture are more likely to be found in the cortex in the superior temporal sulcus, whereas neurons with activity related to facial identity are more likely to be found in the TE areas (Hasselmo et al. 1989; Rolls 2007). Indeed, we can think of the cortex in the superior temporal sulcus as being a more dorsal face processing stream than the stream in the inferior temporal visual cortex (Baylis et al. 1987; Rolls 2012).

Using fMRI in macaques, the segregation of face cells into 6 face patches has been described: 1 posterior (PL), 2 middle (ML, MF), and 3 anterior (AL, AF, AM) (Tsao et al. 2008a, 2014). Neurons in ML and MF are view-specific; neurons in AL are tuned to identity mirror-symmetrically across views, thus achieving partial view invariance; neurons in AM, the most anterior face patch, achieve almost full view invariance and provide a sparse representation of face identity. Neurons in ML/MF respond to both monkey and human faces, whereas in AM many cells are selective for either monkey or human faces.

Human subjects showed 4 face areas or patches (occipital, fusiform, anterior to fusiform, and superior temporal sulcus face areas (Tsao et al. 2008a). In human fMRI studies, evidence for specialization of function related to visual processing in areas similar to those in macaques has been described (Spiridon et al. 2006; Said et al. 2011; Vul et al. 2012; Weiner et al. 2017). The fusiform face area, which corresponds to part of the macaque inferior temporal cortex, is implicated in the processing of face identity. The cortex in the superior temporal sulcus and just above it in the middle temporal gyrus, which corresponds to the macaque cortex in the superior temporal sulcus, is implicated in face expression and gesture (i.e., moving faces) (Critchley et al. 2000), and has reduced functional connectivity in autism (Cheng et al. 2015). An area that may correspond to the macaque inferior temporal cortex has a highly developed representation of objects (Rolls 2012, 2016a). A parahippocampal area is implicated processing spatial scenes and probably corresponds to the macaque parahippocampal gyrus areas in which neurons are tuned to spatial view and to combinations of objects and the places in which they are located (Georges-François et al. 1999; Rolls et al. 2005, 2016a; Kesner and Rolls 2015). This parahippocampal spatial scene area may receive input from an occipito-temporal lateral place patch (Kornblith et al. 2013).

Some of the key discoveries about face-responsive neurons in the anterior parts of the temporal lobe, and in the amygdala and orbitofrontal cortex, are described next.

### The Selectivity of One Population of Neurons for Faces

The neurons discovered as having responses selective for faces are selective in that they respond 2–20 times more (and statistically significantly more) to faces than to a wide range of gratings, simple geometrical stimuli, or complex 3-D objects (Perrett et al. 1982; Rolls 1984, 2007). These neurons are specialized to provide information about faces in that they provide much more information (on average 0.4 bits) about which (of 20) face stimuli is being seen than about which (of 20) nonface stimuli is being seen (on average 0.07 bits) (Rolls et al. 1997a, b, 2007). These information theoretic procedures provide an objective and quantitative way to show what is “represented” by a particular population of neurons (Rolls and Treves 2011).

### Neurons Selective for Individual Face Features or for Combinations of Face Features

Masking out or presenting parts of the face (e.g., eyes, mouth, or hair) in isolation reveal that different cells respond to different features or subsets of features, and some require all the features to be present in the correct spatial configuration (i.e., not jumbled) (Perrett et al. 1982; Rolls 2007).

### Distributed Encoding of Face Identity

An important question for understanding brain function is whether a particular object (or face) is represented in the brain by the firing of one or a few gnostic (or “grandmother”) cells, or whether instead the firing of a group or ensemble of cells each with different profiles of responsiveness to the stimuli provides the representation. It has been

shown that the representation of which particular face is present is distributed. For example, in a study using 23 faces and 45 nonface natural images a distributed representation was found, with rather few stimuli producing high firing rates, and increasingly large numbers of stimuli producing lower and lower firing rates (Rolls and Tovee 1995) (see Fig. 2). Indeed, the firing rate probability distribution of many neurons is approximately exponential (Franco et al. 2007).

Complementary evidence comes from applying information theory to analyze how information is represented by a population of these neurons. The information required to identify which of  $S$  equiprobable events occurred (or stimuli were shown) is  $\log_2 S$  bits. (Thus 1 bit is required to specify which of two stimuli was shown, 2 bits to specify which of 4 stimuli was shown, 3 bits to specify which of 8 stimuli was shown, etc.) The important point for the present purposes is that if the encoding was local (or grandmother cell-like), the number of stimuli encoded by a population of neurons would be expected to rise approximately linearly with the number of neurons in the population. In contrast, with distributed encoding, provided that the neuronal responses are sufficiently independent, and are sufficiently reliable (not too noisy), the number of stimuli encodable by the population of neurons might be expected to rise exponentially as the number of neurons in the sample of the population was increased. The information available about which of 20 equiprobable faces had been shown that was available from the responses of different numbers of these neurons increases approximately linearly with the number of neurons in the population (see Fig. 3), and thus the representational capacity increases exponentially with the number of neurons in the ensemble (Fig. 4) (Rolls et al. 1997a; Rolls and Treves 2011; Rolls 2016a). This is further evidence for distributed encoding, and for the power of the code used.

The code that is used in the inferior temporal visual cortex is primarily the number of spikes from each neuron (i.e., a rate code), for very little (not more than approximately 5% of the total information) was available from stimulus-

### Face Processing in Different Brain Areas and Face Recognition,

**Fig. 2** Firing rate distribution of a single neuron in the temporal visual cortex to a set of 23 face (*F*) and 45 nonface images of natural scenes. The firing rate to each of the 68 stimuli is shown. *P* indicates a face profile stimulus, *B* a body part stimulus such as a hand (After Rolls and Tovee 1995)

dependent synchrony (Rolls and Treves 2011; Rolls 2016a). The same result was found in natural scenes in which two test images had to be segmented from a complex background, the features of each object had to be bound together, and the monkey had to use top-down attention to search for one of two images in a complex scene (Rolls and Treves 2011; Rolls 2016a).

The advantages of the code that has been found include exponentially high coding capacity, readability by a neuronally plausible (synaptically) weighted sum of the firing rates of different neurons, resistance to noise, generalization,

completion, graceful degradation or fault tolerance, and speed of readout of the information, as described elsewhere (Rolls and Treves 2011; Rolls 2016a).

### Invariant Representations

One of the major problems that must be solved by a visual system is the building of a representation of visual information which allows recognition to occur relatively independently of size, contrast, spatial frequency, position on the retina, angle of

**Face Processing in Different Brain Areas and Face Recognition, Fig. 3** (a) The values for the average information available in the responses of different numbers of these neurons on each trial, about which of a set of 20 face stimuli has been shown. The decoding method was dot product (DP, x) or probability estimation (PE, +), and the effects obtained with cross validation procedures utilizing 50% of the trials as test trials are shown. The remainders of

the trials in the cross-validation procedure were used as training trials. The *full line* indicates the amount of information expected from populations of increasing size, when assuming random correlations within the constraint given by the ceiling (the information in the stimulus set,  $I = 4.32$  bits). (b) The percent correct for the corresponding data to those shown in Fig. 3 (After Rolls et al. 1997a)

view, etc. This is required so that if the receiving associative networks (e.g., the amygdala, orbitofrontal cortex, and hippocampus) learn about one view, position, etc. of the object, the organism generalizes correctly to other positions, views, etc. of the object. It has been shown that the majority of face-selective anterior inferior temporal cortex neurons have responses that are relatively invariant with respect to the size of the stimulus, and the exact position of the face on the retina (translation invariance) (Rolls and Baylis 1986; Rolls 2007, 2016a). Interestingly, the receptive fields become smaller (and still include the fovea) when faces or objects are seen against a complex natural background, and this helps with the binding problem (Aggelopoulos

et al. 2005). It makes the interface to action simpler, in that what is at the fovea can be interpreted (e.g., by an associative memory in the orbitofrontal cortex or amygdala) partly independently of the surroundings, and choices and actions can be directed if appropriate to what is at the fovea (Rolls 2007, 2016a). Some neurons have view invariant responses to faces (which would be useful for face recognition, and indeed these neurons tend to be tuned to face identity) (Hasselmo et al. 1986; Rolls 2000). Other neurons have view-specific responses, and indeed are found in the cortex in the superior temporal sulcus where some neurons are tuned to face expression, and typically to face motion and face gesture (change of expression), all of which are important

in social interactions (Hasselmo et al. 1989; Rolls 2007, 2016a). These discoveries have been confirmed (Said et al. 2011; Polosecki et al. 2013; Tsao 2014).

A computational model of how invariant representations for faces and objects are built in the ventral visual system can account for the responses of many of these neurons. The model,

**Face Processing in Different Brain Areas and Face Recognition, Fig. 4** The number of stimuli (in this case from a set of 20 faces) that are encoded in the responses of different numbers of neurons in the temporal lobe visual cortex, based on the results shown in Fig. 3. The decoding method was dot product (DP, open circle) or probability estimation (PE, filled circle) (After Rolls et al. 1997a)

VisNet, utilizes competitive learning at each stage of the hierarchy of visual cortical areas in the ventral visual system with convergence from stage to stage to form feature combination neurons, and slow learning implemented by an associative synaptic learning rule with a short-term trace memory of previous activity to enable the learning of invariant representations (Wallis and Rolls 1997; Rolls 1992, 2012, 2016a) (Fig. 5). Consistent with this, macaque face cells respond to combinations of several metric properties of human faces (Chang and Tsao 2017). VisNet can locate and identify objects and people in complex scenes by adding an emulation of the dorsal visual system to foveate salient stimuli (Rolls and Webb 2014). VisNet can also learn deformation-specific representations of pose, which are likely to be useful for the emotional and intentional interpretation of faces and people (Webb and Rolls 2014).

**A Representation of Faces in the Amygdala**

Outputs from the temporal cortical visual areas reach the amygdala, and evidence is accumulating that these brain areas are involved in social and

**Face Processing in Different Brain Areas and Face Recognition, Fig. 5** Right. Schematic diagram showing convergence achieved by the forward projections in the visual system, and the types of representation that may be built by competitive networks operating at each stage of the system from the primary visual cortex (V1) to the

inferior temporal visual cortex (area TE) (see text). LGN lateral geniculate nucleus. Area TEO forms the posterior inferior temporal cortex. The receptive fields in the inferior temporal visual cortex (e.g., in the TE areas) cross the vertical midline (not shown). Left. Hierarchical network structure of VisNet (See Rolls 2012)

emotional responses to faces (Rolls 2014). For example, we have identified a population of neurons with face-selective responses in the primate amygdala, some of which may respond to facial and body gesture (Leonard et al. 1985). In humans, amygdala damage can impair the recognition of fear face expressions, and extraversion influences whether activations will be found to happy faces (Rolls 2014).

## A Representation of Faces in the Orbitofrontal Cortex

Rolls et al. (2006) have found a number of face-responsive neurons in the orbitofrontal cortex, and they are also present in adjacent prefrontal cortical areas (Rolls 2007, 2016a). The orbitofrontal

cortex face-responsive neurons, first observed by Thorpe et al. (1983), tend to respond with longer latencies than temporal lobe neurons (140–200 ms typically, compared with 80–100 ms) and can convey information about which face is being seen, by having different responses to different faces. Some of the orbitofrontal cortex face-selective neurons are responsive to face gesture or movement and others to face expression (Rolls et al. 2006). The findings are consistent with the likelihood that these neurons are activated via the inputs from the temporal cortical visual areas in which face-selective neurons are found. The significance of the neurons is likely to be related to the fact that faces convey information that is important in social reinforcement, both by conveying face expression, which can indicate reinforcement, and by encoding information about

**Face Processing in Different Brain Areas and Face Recognition, Fig. 6** Social reversal task: The trial starts synchronized with the scanner and two people with neutral face expressions are presented to the subject. The subject has to select one of the people by pressing the corresponding button, and the person will then either smile or show an angry face expression for 3000 ms depending on the current mood of the person. The task for the subject is to keep track of the mood of each person

and choose the “happy” person as much as possible (*upper row*). Over time (after between 4 and 8 correct trials) this will change so that the “happy” person becomes “angry” and vice versa, and the subject has to learn to adapt her choices accordingly (*bottom row*). Randomly intermixed trials with either two men, or two women, were used to control for possible gender and identification effects, and a fixation cross was presented between trials for at least 16,000 ms (After Kringelbach and Rolls 2003)

which individual is present, also important in evaluating and utilizing reinforcing inputs in social situations (Rolls 2014). The existence of these neurons has been confirmed using fMRI (Tsao et al. 2008b).

We have also been able to obtain evidence that nonreward used as a signal to reverse behavioral choice is represented in the human orbitofrontal cortex (see Rolls 2014). Kringelbach and Rolls (2003) used the faces of two different people, and if one face was selected then that face smiled, and if the other was selected, the face showed an angry

expression. After good performance was acquired, there were repeated reversals of the visual discrimination task. Kringelbach and Rolls found that activation of a lateral part of the orbitofrontal cortex in the fMRI study was produced on the error trials, that is when the human chose a face, and did not obtain the expected reward (see Figs. 6 and 7). The investigation reveals that the human orbitofrontal cortex is very sensitive to social feedback when it must be used to change behavior (Rolls 2014) and that provides some evidence for the theory that

**Face Processing in Different Brain Areas and Face Recognition, Fig. 7** Social reversal: Composite figure showing that changing behavior based on face expression is correlated with increased brain activity in the human orbitofrontal cortex. (a) The figure is based on two different group statistical contrasts from the neuroimaging data which are superimposed on a ventral view of the human brain with the cerebellum removed and with indication of the location of the two coronal slices (b, c) and the transverse slice (d). The red activations in the orbitofrontal cortex (denoted OFC, maximal activation:  $Z = 4.94$ ;  $42, 42, -8$ ; and  $Z = 5.51$ ;  $x, y, z = -46, 30, -8$ ) shown on the rendered brain arise from a comparison of reversal events with stable acquisition events, while the blue activations in the fusiform gyrus (denoted Fusiform, maximal activation:  $Z > 8$ ;  $36, -60, -20$  and  $Z = 7.80$ ;  $-30, -56, -16$ ) arise from the main effects of face expression. (b) The coronal slice through the frontal part of the brain shows the cluster in the right orbitofrontal cortex across

all nine subjects when comparing reversal events with stable acquisition events. Significant activity was also seen in an extended area of the anterior cingulate/paracingulate cortex (denoted cingulate, maximal activation:  $Z = 6.88$ ;  $-8, 22, 52$ ; green circle). (c) The coronal slice through the posterior part of the brain shows the brain response to the main effects of face expression with significant activation in the fusiform gyrus and the cortex in the intraparietal sulcus (maximal activation:  $Z > 8$ ;  $32, -60, 46$ ; and  $Z > 8$ ;  $-32, -60, 44$ ). (d) The transverse slice shows the extent of the activation in the anterior cingulate/paracingulate cortex when comparing reversal events with stable acquisition events. Group statistical results are superimposed on a ventral view of the human brain with the cerebellum removed, and on coronal and transverse slices of the same template brain (activations are thresholded at  $P = 0.0001$  for purposes of illustration to show their extent) (After Kringelbach and Rolls 2003)

depression is related to overactivity in a lateral orbitofrontal cortex nonreward attractor network (Rolls 2016b).

To investigate the possible significance of the neurons in the orbitofrontal cortex with face-related inputs, we also tested the responses to faces of patients with orbitofrontal cortex damage. We included tests of face (and also voice) expression decoding, because these are ways in which the reinforcing quality of individuals is often indicated. Impairments in the identification of facial and vocal emotional expression were demonstrated in a group of patients with ventral frontal lobe damage who had socially inappropriate behavior (Rolls 2007, 2014). The expression identification impairments could occur independently of perceptual impairments in facial recognition, voice discrimination, or environmental sound recognition. The face and voice expression problems did not necessarily occur together in the same patients, providing an indication of separate processing.

To obtain clear evidence that the changes in face and voice expression identification, emotional behavior, and subjective emotional state were related to orbitofrontal cortex damage itself, and not to damage to surrounding areas which is present in many closed head injury patients, we performed further assessments in patients with circumscribed lesions made surgically in the course of treatment (Hornak et al. 2003). We found that some patients with bilateral lesions of the orbitofrontal cortex had deficits in voice and face expression identification (Hornak et al. 2003). (The same group of patients had deficits on a probabilistic monetary reward reversal task, indicating that they have difficulty not only in representing reinforcers such as face expression but also in using reinforcers (such as monetary reward) to influence behavior.) Some patients with unilateral damage restricted to the orbitofrontal cortex also had deficits in voice expression identification. Patients with unilateral lesions of the anteroventral part of the anterior cingulate cortex and/or medial prefrontal cortex area BA9 were in some cases impaired on voice and face expression identification.

## **“Concept Cells” Recorded in Humans: Correspondence with Object-Place Memory-Related Neurons in Macaques**

Some neurons in the human medial temporal lobe, in structures that include parahippocampal regions, respond to the faces of particular individuals, such as Jennifer Aniston (Quiroga 2012). These neurons are multimodal, in that they may respond to the voice of the person, and to the place associated with a person, and have been termed “concept cells” (Quiroga 2012). These neurons thus appear to correspond to the hippocampal/parahippocampal system memory-related neurons in macaques, which respond to an object or the place in which it is located, and which are part of an episodic memory system (Georges-François et al. 1999; Rolls et al. 2005; Kesner and Rolls 2015; Rolls 2016a). These neurons, like face neurons, use sparse distributed encoding, and are not grandmother cells (Quiroga et al. 2008).

## Face-Selective Neurons: Comparative Perspectives

William James Clark and Michael Colombo  
Department of Psychology, University of Otago,  
Dunedin, New Zealand

### Synonyms

Extrastriate cortex; Face cell; Facial recognition; Grandmother cell; Visual processing

### Introduction

Of all the biologically relevant visual categories that surround humans and other animals,

faces convey the most information required to successfully navigate the social environment. For instance, recognition of a conspecific or an approaching predator, interpretation of emotional expressions, the direction of eye gaze, and selection of an appropriate mate are all critically dependent on facial cues. Indeed, specialized neural circuits have evolved for the processing of faces within the visual systems of a number of species (see Freiwald and Tsao 2010, and references therein). For example, many animals attend preferentially to faces from birth or, at least, exhibit the neural foundations required to recognize a face during the earliest stages of development (Srihasam et al. 2014). Such predispositions to faces evoke the notion of “grandmother cells,” hypothetical neurons that code for a single complex stimulus across changing viewpoints, such as one’s grandmother (Gross 2002). As we shall see, although face cells do respond in a highly selective manner to faces as a stimulus category (Gross 2008), and while they may be mediating animals’ remarkable abilities of facial perception, face-selective neurons are not quite these hypothesized, highly invariant “grandmother cells.”

## The Origins of the Grandmother Cell Hypothesis

Jerzy Konorski, a Polish neuroscientist, expanded on the theories of William James, who postulated that certain cells within the brain may represent conscious experiences or percepts (James 1890). Firstly, Konorski (1967) capitalized on the findings of Hubel and Wiesel (1965) that there was a progressive increase in the complexity of a cell’s receptive field from the retina to area V3 and reasoned that higher visual areas beyond V3, such as the inferior temporal (IT) cortex, would continue the trend of increasing complexity (see Gross 2002, and references therein). Secondly, Konorski (1967) noted that only IT cortex lesions correlated specifically with visual abnormalities in recognition and discrimination learning. Finally, Konorski (1967) inferred from his own clinical work that prosopagnosia, a difficulty in recognizing faces, was also associated with IT

cortex damage (Konorski 1967). These three lines of evidence lead Konorski to predict that “perceptions experienced in humans’ and animals’ lives, are represented not by the *assemblies* of units but by *single units* at the highest levels of particular analyzers” (Konorski 1967, p. 74). Konorski named the specialized cells “gnostic units” and suggested that they were organized in areas called “gnostic fields,” that these fields were located in the ventral temporal lobe, and that each field represented a different biologically relevant perceptual category, such as emotional expressions, locations, hands, and faces (Konorski 1967). Konorski asserted that destruction of a gnostic field dedicated to faces in IT cortex would manifest as prosopagnosia (Konorski 1967). Konorski’s (1967) early speculations on the location of the facial processing circuitry were astoundingly similar to our modern understanding (Gross 2002).

In parallel to Konorski’s (1967) work, Jerry Lettvin pioneered single-cell recording in the frog retina, found that certain cells only responded to small dark spots in the visual field, and hypothesized these cells to be acting as specialized bug detectors (Lettvin et al. 1961). Interested by these neuron’s selectivity and the related work of Hubel and Wiesel (1965), Lettvin predicted the existence of “grandmother cells” that could represent the highest order of perceptual categories (Gross 2002, and references therein). Therefore, much as Konorski (1967), Lettvin asserted that cells in the visual system must exist that respond to a single individual, despite changes in viewpoint, color, and other arbitrary features (Gross 2002, and references therein).

### “Where” and “What” Visual Pathways

To understand how face-selective neurons function in facial recognition, it is necessary to understand the structure of the mammalian visual system. Prior to the late 1960s, vision was regarded as a functionally homogenous system, with object and location coding occurring across the same regions of visual cortex (Ungerleider and Haxby 1994). Schneider (1969) was the first to challenge the prevailing view by training

Syrian hamsters on two tasks, one requiring orienting to a sunflower seed held overhead, the other requiring discrimination between two differently patterned doors in a two-arm maze. The hamsters were then given bilateral lesions to the superior colliculus and visual cortex. Superior colliculus lesions impaired the ability to spatially localize the seed but did not impair performance on the pattern discrimination task. Visual cortex lesions, on the other hand, disrupted pattern discrimination learning but not performance on the spatial localization task. The double dissociation suggested that two separate subcortical pathways exist in the hamster: a colliculo-pulvinar-cortical pathway processing “where” information and the geniculostriate pathway processing “what” information. The colliculo-pulvinar-cortical pathway projects from the retina to the pulvinar nucleus of the thalamus and finally propagates to the extrastriate visual processing areas (Ungerleider and Haxby 1994). In contrast, the geniculostriate pathway projects from the optic nerve to the lateral geniculate nucleus of the thalamus and finally to the primary visual cortex (V1) (Ungerleider and Haxby 1994, and references therein). Similar findings were made by Ungerleider and Mishkin (1982), who showed that IT cortex lesions impaired performance on an object discrimination task, but not a spatial localization task, whereas parietal lesions impair spatial localization but not object discrimination.

Schneider’s (1969) discovery of separate subcortical routes from retina to cortex is now recognized as a universal organization of the mammalian visual system. The double dissociations noted by Schneider (1969) and Ungerleider and Mishkin (1982) have led to the proposal that visual information is processed along two different cortical streams: a dorsal (“where”) pathway that projects from the primary visual cortex to the inferior parietal lobe and is responsible for spatial localization and a ventral (“what”) pathway that projects from the primary visual cortex to IT cortex and is responsible for pattern perception (Ungerleider and Haxby 1994, and references therein).

## Face-Selective Neurons in Nonhuman Primates

Charles Gross performed pioneering electrophysiological recordings in IT cortex and the adjacent dorsal bank of the superior temporal sulcus (STS) of macaques in the late 1970s and early 1980s, revealing populations of neurons that responded selectively to faces (see Fig. 1) and body parts (see Gross 2008, and references therein). The receptive fields of face-selective neurons in IT cortex encompassed most of the visual field and were always localized within the fovea, consistent with their role in complex pattern recognition. Many face cells in IT cortex were sensitive to a face's orientation. For example, some units fired only or maximally to faces viewed in portrait or profile viewpoints (viewer centered), while others responded to faces in both viewpoints (object centered). Removal of facial features such as the eyes and mouth or the presentation of a line-drawn caricature of a face elicited reduced responses from face cells, suggesting that face cells summate incoming visual information about the components of faces.

While the aforementioned studies indicated that the primary role of face cells in IT cortex is in the recognition of an individual, whereas face cells in STS work in parallel to interpret emotional expression and the direction of eye gaze, it remained unknown if face cells were casual in the perception of faces. To examine the notion of causality, Afraz et al. (2006) applied electrical microstimulation to sites that contained clusters of face cells and non-face cells within IT cortex of macaque monkeys during a categorization task that required discriminating between images of face and non-face objects. Stimulation applied to face-selective sites, but not non-face-selective sites, biased the monkeys' decisions heavily toward the face category, thereby establishing a causal role for the activity of face-selective neurons in mediating the perception of faces.

The next challenge was to determine the spatial location of face-selective sites in IT cortex and if these sites were in conserved locations across all primates. Freiwald and Tsao (2010) used fMRI to reveal that face-selective neurons in IT cortex

reside in a series of six anatomically and functionally connected clusters, known as "face patches." A similar series of six face patches were subsequently discovered in IT cortex of the marmoset (a New World monkey), suggesting that the foundations of the face processing system were present in our anthropoid primate ancestors over 35 million years ago (Hung et al. 2015). Examining the role of face patches further, Chang and Tsao (2017) demonstrated that face-selective neurons in most of the face patches represent a combination of facial features (e.g., eyes, nose, and mouth shape) in a specific viewpoint. In contrast, face-selective neurons in the face patch at the final output of IT cortex represent a combination of facial features across any viewpoint. Thus, the face patches work together to build a point-by-point 3-D representation of a face, allowing primates to recognize an individual across changing viewpoints. Chang and Tsao's (2017) discovery demonstrates that face-selective neurons are face-component neurons. As such, face cells are not really "grandmother cells" as originally conceived. Rather, each face cell performs a specific analytic role within an ensemble across IT cortex, synthesizing the emergent property of facial identity.

## Face Processing in the Human Brain

Given the wealth of evidence in nonhuman primates documenting a specialized circuitry for the perception of faces, it was natural to wonder whether a corresponding series of areas exist in the human brain. Initial investigation using fMRI revealed a distinct area in the right fusiform gyrus, now known as the fusiform face area (FFA), that was reliably activated specifically to face stimuli (Kanwisher et al. 1997). Subsequent fMRI work determined that the FFA is homologous with the face patch at the final output of IT cortex in macaques, the patch that facilitates individual recognition across changes in viewpoint (see Freiwald and Tsao 2010, and references therein). In addition to the FFA, the STS is also highly responsive to faces, and is likely responsible, as in monkeys, for the processing of emotional

**Face-Selective Neurons: Comparative Perspectives, Fig. 1** Example of an IT cortex neuron that responded more strongly to the front view of faces than to any other stimulus tested. The stimuli were interleaved colored slides projected onto the fovea for 2.5 s, as indicated by the horizontal lines under each histogram. **(a)** Responses of an IT neuron to a monkey face in different degrees of rotation (bottom), and a line graph (top) depicting the firing

rate to each of the different rotations of the monkey face, as well as the firing rate when the eyes were removed (NE) and to a brush (BR). **(b)** Responses of an IT neuron to altered faces, faces with components removed, a human face, and a hand (bottom) and a bar graph (top) depicting the firing rate to each of the different stimuli (Reprinted with permission from Gross 2008)

expression and direction of eye gaze (see Kanwisher et al. 1997, and references therein).

Unlike in nonhuman primates, in humans there are far fewer opportunities to analyze the activity of single cells within the extrastriate visual cortex. Nevertheless, Schalk et al. (2017) performed a landmark case study to determine if neurons in the FFA were specifically involved in facial recognition. Electrical stimulation was applied to face-selective and non-face-selective visual areas of a neurosurgical patient while viewing the experimenter's face, as well as a series of non-face objects (a box, ball, or kanji symbol). Stimulation of face-selective areas while viewing the experimenter's face elicited consistent reports of changes in the appearance of the experimenter's facial features. Stimulation of face-selective areas while viewing non-face objects resulted in the patient reporting hallucinations of a whole or partial face (known as facephenes) superimposed over the non-face objects; these facephenes did not occur when stimulation was applied to non-face-selective visual areas. Schalk et al.'s (2017) case study established that the activity of face-selective neurons in the FFA of humans are, much like in nonhuman primates, causal in the perception of faces.

## Face-Selective Neurons in Other Mammalian Species

The only reports of face-selective neurons other than in primates are from the extrastriate visual cortex of sheep (Kendrick and Baldwin 1987). Face-selective neurons were isolated across the temporal cortex and exhibited very similar basic response properties to those found in primates. A subpopulation of the face cells were tuned to the size of a sheep's horns, a feature that conveys information on gender and position in a sheep's dominance hierarchy. Most face cells responded preferentially to conspecifics faces, while a smaller number also fired to human and sheepdog faces. Interestingly, the neuronal responses to familiar sheep, human, and sheepdog faces were significantly greater than to unfamiliar faces

(Peirce et al. 2001, and references therein). Landi and Freiwald (2017) determined that familiar faces also cause significantly greater activation of face-selective neurons in the face patches of macaque IT cortex. The strikingly similar effect of familiarity on the neuronal responses to faces in sheep and macaques suggests both species possess separate mechanisms for general and familiar face recognition.

Regions sensitive to faces have also been observed in dogs. Cuaya et al. (2016) used fMRI imaging to reveal an area in the ventral temporal cortex of domestic dogs that exhibited significantly greater activation to human faces than non-face visual stimuli. Dogs are easily able to visually discriminate between different human faces, as well as detect subtle changes in eye gaze direction and emotional expressions based on human facial cues. It is possible that dogs' long history of mutual attachment with humans has facilitated the appearance of neural circuits that process human faces. It is currently undetermined whether the same area of temporal cortex active to human faces in dogs is also active to dog faces. Given that face-selective areas in the sheep temporal cortex contain neurons that respond to the faces of other species (Kendrick and Baldwin 1987), it seems likely that a general face processing system has evolved in the temporal cortex of all mammals.

## Do Birds Possess Face-Selective Neurons?

Birds are one of the few classes of vertebrates that possess a visual system comparable to primates in complexity. Despite the fact that the last common ancestor of mammals and birds existed around 300 million years ago, many structures of the avian visual system are considered functionally homologous to areas of the mammalian visual pathways (Stacho et al. 2016, and references therein). For example, as in mammals, there are two main visual pathways in the avian brain. The thalamofugal pathway, similar to the mammalian geniculostriate pathway, projects

from the retina to the principal optic nuclei and then to the visual wulst in the telencephalon (Fig. 2; Stacho et al. 2016, and references therein). The tectofugal pathway, similar to the primate colliculo-pulvinar-cortical pathway, travels from the retina to the optic tectum and then to the nucleus rotundus of the thalamus, and from there to a structure known as the entopallium (ENTO), and finally to three visual association areas: the mesopallium ventrolaterale (MVL), area temporo-parieto-occipitalis (TPO), and the

nidopallium frontolaterale (NFL) (Fig. 2; Stacho et al. 2016, and references therein).

Lesions to the ENTO cause an array of visual deficits, consistent with a complex visual processing structure (Nguyen et al. 2004). For instance, ENTO lesions impair performance on psychophysical tasks of visual acuity, intensity threshold discriminations, and pattern and color discriminations, with the magnitude of the deficits correlated with the extent of damage (see Bessette and Hodos 1989, and references therein). As in

**Face-Selective Neurons: Comparative Perspectives, Fig. 2** Anatomical and functional similarities of the thalamofugal and tectofugal pathways in birds (left), and geniculo-striate and colliculo-pulvinar-cortical pathways in mammals (right). The entopallium (ENTO) is comparable with the early extrastriate regions of the mammalian

visual system. Area temporo-parieto-occipitalis (TPO), the mesopallium ventrolaterale (MVL), and nidopallium frontolaterale (NFL) receive projections from the ENTO and are likely involved in processing higher-order aspects of form, color, and motion information

mammals, there is segregation of incoming visual information into separate form, color, and motion parallel processing streams in the ENTO (Nguyen et al. 2004) that is likely maintained into the higher visual areas MVL, TPO, and NFL (Stacho et al. 2016). Fewer studies have been conducted on the MVL, TPO, and NFL, but those that have (Stacho et al. 2016; Koenen et al. 2016) further support the view that these areas are functionally similar to areas of the mammalian extrastriate cortex.

A plethora of behavioral studies using pigeons and Japanese quail suggest faces play a critical role in conspecific recognition and social signaling for birds (Shimizu et al. 2010, and references therein). Likewise, as a bird's face comprises a series of distinct local features, such as the beak, eyes, plumage, and cere (exposed skin on the upper beak), it is possible that a corresponding series of neural circuits in the avian brain analyses these local facial features within their global configuration. Indeed, ENTO lesions in pigeons impair the ability to discriminate between two conspecific pigeons or between two separate avian species (Java sparrow vs. gray starling), but not the ability to discriminate between food/nonfood object categories, or between a pigeon and a different avian species (see Watanabe 1996, and references therein). Despite the aforementioned evidence that processing faces is important for birds, the only study that has investigated face cells in the avian visual system failed to find any evidence of face-selective neurons (Scarf et al. 2016). It is possible that neural circuits dedicated to the processing of faces in birds reside upstream of ENTO in higher visual association areas, such as NFL, MVL, and TPO. Indeed, Marzluff et al. (2012) demonstrated significant neuronal activation of the NFL and MVL of crows in response to viewing human faces using positron emission tomography (PET) brain imaging. However, as the crows were not presented with any non-facial stimuli, or indeed even crow faces, it is unclear if the activity is representative of areas specialized for face perception as opposed to processing complex visual information, as would be expected from regions functionally similar to extrastriate cortex.

## Lateralization of Face Processing

Across all vertebrates that rely on vision for social recognition, there are significant differences in the ability of the left and right cerebral hemispheres to process face information. Nonhuman primates (Freiwald and Tsao 2010), humans (Kanwisher et al. 1997), sheep (Peirce et al. 2001), and domesticated dogs (Cuaya et al. 2016), all exhibit greater right hemisphere activation when viewing faces, an effect that is associated with the global processing of faces as a combination of local component features (Chang and Tsao 2017). In support of global processing, the ability of nonhuman primates, humans, and sheep to recognize faces (Brecht et al. 2017, and references therein) is significantly impaired when viewing an inverted face, suggesting that all mammals process faces in a global manner.

Interestingly, pigeons categorize visual stimuli based on their local features over their global configuration, an effect associated with a left hemispheric dominance of visual discrimination and learning in birds (see Scarf et al. 2016, and references therein). The predisposition to attend to local features over the global configuration also appears to extend to faces. For instance, it was recently demonstrated that a crow's ability to discriminate between upright and inverted images of crow and human faces was unimpaired by the inversion of the faces, a finding that stands in contrast to that observed in mammals (Brecht et al. 2017, and references therein). Thus, in contrast to mammals, birds may process faces more at the level of individual features and that might explain why Scarf et al. (2016) failed to find any face-selective neurons. The study of face-selective neurons in the avian brain is still in its infancy, and further studies examining how cells in higher association areas of the avian visual system respond to faces are required.

## Concluding Thoughts

In summary, over 50 years of research into the extrastriate visual areas of the vertebrate brain has unequivocally shown that face-selective neurons

mediate facial recognition. Face-selective neurons do not represent “grandmother cells,” but nevertheless respond with astounding specificity to faces over any other complex stimulus. The computational goal of such neurons in the visual system is not to encode particular individuals, but rather to create a flexible neural code representative of a given face that is forwarded downstream for further mnemonic and cognitive appraisal. Most of our current understanding of face-selective neurons comes from functional imaging and electrophysiological studies in nonhuman primates. While there have been preliminary investigations in other mammalian and avian species, the absence of sufficient comparative data makes it difficult to assess the evolutionary origins of the face processing system across vertebrates. Birds are of particular interest in the search for face-selective neurons, given their highly developed visual system and divergent cortical organization from mammals. While there is much we do not understand of visual processing and beyond, the stage has been set to determine whether face-selective neurons represent a universal individual recognition solution across the animal kingdom.

## Facultative Polyandry/ Strategic Pluralism

Kevin A. Rosenfield

### Synonyms

Alternative reproductive strategies; Context-dependent strategies; Extra-pair copulation

### Facultative Polyandry

Traits that are expressed in contexts in which they are potentially advantageous, and suppressed at other times, are referred to as **facultative** traits. In mating systems with female **polyandry** (from Greek: poly- “many” + andr- “male”), females mate with multiple males within a breeding period (Barrows 2011). **Facultative polyandry** is therefore a female mating strategy wherein normally monogamous females mate with multiple males within a breeding period. In a large number of species, including many birds and mammals, pair-bonded females practice facultative polyandry (e.g., birds, Yezerinac et al. 1995; humans, Scelza 2011; marmots, Graziani et al. 1998).

### Flexible Mating Systems

Facultative polyandry is an example of behavioral flexibility in animal mating systems. **Strategic pluralism** theory posits that such flexibility is adaptive because it allows animals to pursue alternatives to their primary strategies when social or environmental factors change (Gangestad and Simpson 2000). Males’ and females’ primary mating strategies are generally attributed to differences in reproductive potential: due to sex differences in the biology of reproduction, males may benefit from mating with multiple females by producing more

offspring, whereas females generally cannot increase their reproductive output by mating with more than one male (Andersson 1994). This fundamental biological difference has led to two widely accepted assumptions: females should form long-term pair-bonds, and males should mate with as many females as possible. However, as suggested by strategic pluralism theory and the occurrence of facultative polyandry, animals’ mating behavior can be highly flexible, and alternative mating strategies may, under certain ecological conditions, be preferable to primary strategies.

### Monogamy, Polyandry, and the Ecology of Facultative Polyandry

Sexually monogamous females ensure that the offspring they produce will be sired by their primary mates. Males can provide direct benefits, such as parental investment, and are more likely to do so when they are certain of paternity (Arnqvist and Kirkpatrick 2005). They are also far less likely to intentionally injure or kill their own offspring and may even protect them from threats by conspecifics or predators. However, if the primary mate of a monogamous female dies, invading males are unlikely to protect, and may be more likely to kill, the dependent offspring of her former mate. In addition, by being limited to a single mate, females risk choosing a male of low genetic quality and passing low-quality genes on to their offspring (Clutton-Brock 2016).

Under polyandry, the costs and benefits are reversed. By mating with multiple males, females may incite sperm competition, potentially leading to fertilization by a male with relatively high genetic quality (Zuk 2003). Furthermore, the total risk of infanticide may be reduced when females are polyandrous, as killing an infant that he may have sired risks a substantial reduction in a male’s reproductive success. Because no particular male can be especially confident of paternity, however, paternal investment is less prevalent in polyandrous species (Clutton-Brock 2016; Kappeler 2012).

In most species, neither strict monogamy nor extreme polyandry is the ideal strategy. Females may be primarily monogamous to secure direct benefits such as paternal care but seek extra-pair copulations when they have mates with low genetic quality. In this way, facultative polyandry serves as an intermediate strategy that may allow females to secure the social benefits of monogamy while also seeking the genetic benefits of polyandry on an opportunistic basis.

## Facultative Trait

Sarika Srivastava and Poonam Singh  
Zoology Section, Mahila Mahavidyalaya,  
Institute of Science, Banaras Hindu University,  
Varanasi, UP, India

## Definition

The word “facultative” originated from the New Latin word *facultātīvus* which means “optional,” the process in which an organism could perform optionally in response to a particular situation rather than by nature (<http://www.dictionary.com/browse/facultative>).

In biology, “facultative trait” can be defined as the efficiency of an organism to survive into more than one specific set of environmental conditions (<http://www.dictionary.com/browse/facultative>).

## Introduction

The facultative trait evolves according to a change in the surrounding environment at a particular time. The first example is that in bright light, a person's eyelids shrink together tightly to protect the eyes until unless he cannot adjust to that light. Another example is that in a colder atmosphere, person's nails turn purple. These two examples are showing facultative adjustments because in both situations, the body adjusts its phenotype according to the particular environment.

In other words, we can say that the facultative trait is a general competent character of any organism, which is not restricted by particular function or mode of life. Facultative trait may be used in many ways at different places. Some examples are as follows, to understand more about this aspect.

### Examples of Facultative Trait

1. **Facultative anaerobe** – Facultative anaerobes are organisms which use oxygen for energy production but also capable to survive in anaerobic condition due to having anaerobic methods of energy production.
2. **Facultative biped** – Facultative biped is an animal that can walk or run on two legs as well as on four limbs according to own specific situation.
3. **Facultative carnivore** – Facultative carnivores do not depend merely on animal flesh for food. They also can survive on nonanimal food. We can compare omnivores with facultative carnivores.
4. **Facultative heterochromatin** – Heterochromatin is a supercoiled structure of DNA or condensed DNA which is less or not active. Facultative heterochromatin is also tightly packed but in the form of non-repetitive DNA which may lose its condensed structure and become transcriptionally active like a euchromatin (Volpe et al. 2002).
5. **Facultative parasitism** – Depending on a particular environmental condition, facultative parasites can survive in both free-living and parasitic condition. This kind of trait shows competitive intermediate state among both the free-living and fully parasitic way of life (Luong and Mathot 2019).

It has been reported that facultative parasites are those who can live their entire life without a host but can also seize the opportunity of hosts and can be parasitic under favorable conditions. For example, some moribund juveniles of nematodes having parasitic characters similar to that of dauer larvae generally formed under tough

situations like high nematode density, low food availability, heat stress, etc. Simultaneously under favorable conditions, these parasites can also live entirely free without a host (Viney 1996; Stasiuk et al. 2012).

6. **Facultative pathogens** – Some bacterial species which are pathogenic and may reproduce in environmental resources such as water, soil, etc. On the other hand, they can also cause disease after getting entry into the vulnerable host. Such kinds of pathogens are known as facultative pathogens (Alberts et al. 2002).
7. **Facultative parthenogenesis** – Parthenogenesis is a mode of asexual reproduction in which female reproduces their offspring without any genetic involvement of a male, e.g., squamate (Snakes and Lizards). Sexually reproducing species like Komodo dragon and several species of snakes are also capable of parthenogenesis in the absence of male partner via mechanism known as half-cloning (a haploid polar body formed due to normal female meiotic divisions fuses with the egg to form a diploid nucleus); this ability is known as facultative parthenogenesis (Ross et al. 1997; Lampert 2008; Laurie and Caldwell 2013).
8. **Facultative parental care** – According to Kolliker (2007), the survival of offspring totally depend on parental care as offspring cannot survive in the absence of their parents, but there are several animals including insects like *N. pustulatus* which appear to be facultative in parental care. Earwig belonging to order Dermaptera show higher variation in maternal care as some of them furnished and defend their nymph, but others terminate care soon after hatching, and even some of them support only at the time of eclosion (Costa 2006; Capodeanu-Nägler et al. 2016).

### Conclusion

From the above discussions, it can be concluded that facultative trait is a special kind of phenotype that might be applied to any organism at any specific time due to changes in environment. It

can be in the form of behavior, different ways of feeding and reproduction for subsistence or any genotypic phenomenon, and many more to survive or to be the fittest. Basically facultative trait is an efficiency to perform optionally in response to particular situation for existence.

## Falconiformes Cognition

Laura Marina Biondi

Instituto de Investigaciones Marinas y Costeras (CONICET- Universidad Nacional de Mar Del Plata), Mar del Plata, Argentina

## Introduction

The order Falconiformes are represented by the diurnal birds of prey belonging to the Falconidae family, with three recognized subfamilies: Falconinae with 46 species (i.e., falcons), Herpetotherinae with 8 species (i.e., laughing falcon and forest falcons), and Polyborinae with 11 species (i.e., caracaras) (Fuchs et al. 2015). Even though originally this order also included the families Accipitridae, Cathartidae, Sagittariidae, and Pandionidae, recent analyses showed that Falconidae are not a sister taxon of Accipitridae (and the rest of the diurnal bird of prey families), but rather a separate lineage in the terminal landbird clade which includes Psittaciformes and the Passeriformes (Jarvis et al. 2014; Prum et al. 2015).

These raptors species represent a highly versatile group of predatory birds with a broad range of sizes and lifestyles: there are species with a weight close to 2000 g, like the Gryfalcon (*Falco rusticolus*), as well as sparrow-size raptors, like the White-fronted Falconet (*Microhierax latifrons*) or the Black-thighed Falconet (*Microhierax fringillarius*). The habitat type used is also variable, which goes from rain forests

to arid steppes and savannas, and many species have also successfully colonized urbanized environments. Moreover, this raptor order includes species with diverse trophic habits and techniques, which ranges from highly specialized species, like *Ibycter americanus* feeding almost exclusively on hymenopterans, to those that show a remarkable broad diet, like the generalist Caracaras, which food and feeding habits can include a spectrum and breadth exceeding the rest of the Falconiformes species (Ferguson-Lees and Christie 2001). With so many different adaptations, this order, along with the rest of the raptors, has attracted the attention of scientists and people in general for long time. Thus, it is not surprising that extensive research about almost every aspect of their biology and ecology, as well as avian medicine and health, has been performed during the last decades in this group of predators.

One issue in raptor research that has been scarcely studied until now relies on the realm of animal cognition. Cognition is the mechanisms that enable animals to acquire, process, store, and act on information from their environment, which include perception, learning, memory, and decision-making (Shettleworth 2010), processes that determinate behavioral responses. There are numerous recognized cognitive abilities that are underpinned by these processes (Shettleworth 2010), which cannot be directly observed in the phenotype of an individual, so they are evaluated through changes in behavior. These are commonly studied using robust experimental methods designed to measure specific cognitive abilities while keeping under control any other factor extraneous to the question of interest, thus reducing the possibility that performance variability on a cognitive task is due to some other cognitive or noncognitive factors than the investigated ability *per se* (Rowe and Healy 2014). Possibly related to this experimental requirement, raptors have not been considered as a good model taxon for cognitive research mainly because they can be challenging for capturing and handling due to their relative big size and apparently low “docility”; also many of these predators occur at low densities, with wide territories, and some are quite secretive or elusive,

all of which make them difficult to mark and track. Additionally, because raptors are placed in the top of the food-chain, they are considered particularly sensitive to the rapidly human-induced environmental changes, so the effort has been put mainly on their ecological role and requirements to the correct planning of conservation and management strategies. Notwithstanding the above, in last few years there was an increase in the studies about raptors’ cognitive abilities and the role of cognition in helping or hindering the adjustment of these predatory birds to a human-dominated world. These works are described in the next sections.

## Individual Learning

The way an animal reacts to a certain stimulus can be the result from a preexisting bias or predispositions, which are also known as innate or genetic controlled behaviors. Learning is a form of plasticity, described as the capacity to modify behavioral patterns based on individual experience, and involves forming internal representations of new information obtained from the current external and internal environments (Shettleworth 2010). Thus, the ability to learn is an evolutionary adaptation that allows many animals to make short-term behavioral adjustments to changing environments. Both preexisting or innate behaviors and learning operate together to produce many behaviors. The link between these two sources of behavioral outcomes relies on the fact that genes and prior environment influence how an animal is affected by specific experiences, thus determining the possibility of learning (Shettleworth 2010).

Raptors are generally considered as capable of showing highly complex behaviors, from which the best-known and detailed documented are those related to their hunting and feeding techniques (e.g., Newton 1979; Ferguson-Lees and Christie 2001). Much of these are considered as representing species-specific preexisting behavioral patterns, which are perfected through maturation (i.e., cognitive, morphological) and, to a different degree, by experience (e.g., trial and

error learning) (Newton 1979). Nevertheless, as occurs with the majority of the behavioral systems in Falconiformes species, we lack detailed studies about the role of learning in the development of their hunting and feeding techniques.

In this sense, the first ones explore and exploit the learning capability of raptors where people involved in the “art” of falconry, or falconers. This practice (i.e., the hunting of wild animals in their natural state and habitat by means of a trained raptor) has been in existence for more than 3000 years, originating in the Middle East and then spreading throughout all over the world. Thus, this discipline or “art” has a history in almost every continent and culture. Today, falconry is also commonly used as a tool in wild raptors’ rehabilitation and in educational programs. Yet, the basis of the raptor’ training has remained practically unchanged since the earliest days of falconry and involves both classical and instrumental conditioning (Jones 2001). These two methods have been proved highly useful for the analysis of associative learning, which occurs when there is a change in the behavior of an animal as a result of one event being paired with another (Pearce 2008). In classic (or Pavlovian) conditioning, two events that are paired together are a neutral conditioned stimulus (CS) and a biologically significant unconditioned stimulus (US). This pairing of a CS-US results in the CS causing a conditioned response (CR) in the animal, which is the natural respond to the particular US presented (Pearce 2008). In the context of falconry, for example, the trainers can use a visual or acoustic cue (CS) which once released the birds respond by coming to the trainer glove (CR) for a portion of meat (US). Operant or instrumental conditioning is a learning method that occurs through rewards and punishments for behavior. Through operant conditioning, an individual makes an association between a particular behavior and its consequence. This consequence acts as a reinforcement that causes a behavior to occur with greater frequency, or as a punishment which decrease the occurrence of such behavior. In this way, for example, trainers can strengthen a falcon’s behavior of flying until certain height before strike a prey, by releasing the quarry only when

such height is reached. Thus, the behavior of taking an appropriate height is then positively reinforced (Jones 2001).

Instrumental conditioning has also been used as an experimental paradigm to assess the visual acuity in several raptor species (Potier et al. 2020 and references therein). The most commonly used method is a 2-choice discrimination task. An animal is trained to choose between two different simultaneously presented stimuli, usually a grating of black-and-white stripes and a uniform gray field. Once the animal is trained to select the patterned display, the reward trials are repeated using patterns with progressively thinner bars, until the point is reached at which the animal chooses the patterned display no more than 50% of the time respect to the other. The spatial frequency of the grating, which cannot be reliably resolved and discriminated from the uniform gray gives the visual acuity threshold. The analysis of the visual acuity of Falconiformes using this learning method has only been performed in several species (reviewed in Potier et al. 2020), and the data about the speed of association between the correct stimulus and the reward is not available, which is not surprising considering that this work did not have the aim to evaluate the variability of learning ability *per se*. The only study that directly assessed the variability in associative learning in Falconiformes was carried out by Guido and collaborators (Guido and Biondi 2017) in the species *M. chimango*, a highly generalist Falconiformes species. These authors compared the performance during the acquisition of a stimulus-reward association and the posterior capacity of reversing this previously learned association. This experimental approach, known as reversal learning paradigm, represents one of the most common methods used to evaluate cognitive flexibility in animals. First, the authors trained the birds to discriminate between two containers of different color (green and yellow, Fig. 1), with only one of them associated with a reward (meat). When the birds reached a learning criterion of five correct consecutive trials, the color-reward contingency was reversed, and the raptors had to reach the same learning criterion to successfully finish the reversion phase. The

### Falconiformes Cognition,

**Fig. 1** Experimental set-up used during the reversal learning test (**a**) relative location of the boxes in the aviary; (**b**) frontal view of the box showing the two inward swinging doors. (Extracted from Guido et al. (2017))

measurements of learning speed used were the quantity of trials and errors committed before reaching the learning criterion. Furthermore, the authors analyzed the type of errors performed during the reversion phase; that is, perseverative errors, which reflected the capacity to inhibit the previous learnt color-reward association, and the regressive errors, which measure the ability to learn and maintain a new choice after initially shifting away from the previously correct choice. The results from this work showed that all individuals of *M. chimango* were able to acquire a color-reward association and to reverse this previously learnt association, adults and juveniles performing similarly in both learning tasks. Moreover, for this raptor species, reversal was a harder task compared to the initial acquisition phase, being the perseverative errors those that lasted for longest, which indicated that reversal learning speed in *M. chimango* was mainly conditioned by the ability to inhibit a previously acquired response, rather than to produce a new alternative behavioral choice. The authors suggested that this type of reversal learning performance might be of great advantage to the highly generalist lifestyle of this predatory bird, which frequently make use of anthropogenic resources (e.g., garbage), whose spatial and temporal predictability does not follow a natural variation but rather is subject to human

activity, so they must be able to react rapidly to changes in the value of the environmental cues that indicate food and others biologically relevant resources.

### Behavioral Innovation and Problem-Solving

In nature, animals frequently have to confront a range of potential problems that they have to solve to achieve different vital goals, like the access to a valuable food source, find safe shelters, suitable nest sites, etc. Many of these problems may involve situations with certain level of novelty, for which animals may adapt the behavioral patterns already present in their species' repertoire, or develop completely new ones (e.g., novel skills, preferences, behavioral strategies). The capacity of behavioral innovation is widespread across the animal kingdom and is assumed to be a fundamental attribute facilitating animals' adjustment to novel or changing environments, allowing them to invade new habitats, exploit novel resources, and cope with habitat modifications (Griffin and Guez 2014). One of the approaches for the study of innovations that evaluates its functional implications is represented by large-scale multitaxa correlational analyses between

anecdotal reports of novel behavioral patterns, ecological characteristics, and evolutionary parameters (Lefebvre 2011). These studies have shown, for example, that Falconiformes and Accipitriformes represent highly innovative orders, characteristic that also correlate with their high relative forebrain size, a brain structure assumed to play a role in higher cognitive functions (Lefebvre et al. 1997). From a mechanistic approach, the novel problem-solving paradigm (or innovative problem-solving) provides an ecologically meaningful assay for measuring the natural proclivity of animals to innovate (Griffin and Guez 2014) and commonly involves a novel extractive foraging task that has to be solved to reach a valuable reward (e.g., puzzle box with food inside). Although this experimental paradigm has been applied to a taxonomically broad array of species (reviewed in Griffin and Guez 2014), only one Falconiformes species, the Chimango caracara, has been explored regarding their capacity to innovative problem-solving and behavioral flexibility in general. In a series of investigations, Biondi and collaborators (Biondi et al. 2008, 2010a) analyzed the capacity of solving a novel puzzle box containing food, as well as the role of cognitive (i.e., learning) and non-cognitive (age, object neophobia, and explorative behavior) factors known to underpin innovation propensity, of wild-caught adults and juveniles chimangos. The test apparatus was made of a transparent Plexiglass material and has four isolated sections containing pieces of food. Each section could be opened by lifting, pushing, pulling, or sliding the lids, respectively (Fig. 2). The authors first characterized the individuals according to their neophobic response and

exploration tendency. Neophobia, or the level of aversion to novel situations, was measured by recording the latency to feed in close presence of a novel object (Greenberg 1983), whereas explorative behavior was investigated by presenting the chimangos with a number of natural and artificial objects and quantifying the time the birds took to approach and contact these objects, and the time they spend exploring them. A day after the end of these two tasks, the authors tested the chimangos with the puzzle box once per day, during five consecutive sessions. The repetition of the box presentation had the main objective of evaluating the possible improvement in chimangos' performance with experience (i.e., learning). The results from these works evidenced a low neophobic response, a high explorative tendency, and a remarkable capacity of innovative problem-solving in this raptor species. During the box solving attempts, the birds used both the beak and talons to contact the different areas of the box, actions that are highly common in the majority of raptors species during prey manipulation. Also, juveniles were less neophobic, more explorative and showed in general better performance in the innovative problem-solving task than adult chimangos. Regarding this last result, a lower neophobia and a higher solving persistence were the factors that most contributed to the enhanced performance observed in young raptors. Furthermore, individual performance improved with experience, as indicated by the progressive reduction in feeding latency across days and by the increase of success in lids opening during subsequent sessions. Although more controlled studies on the cognitive mechanisms involved are needed, the authors suggested that following the

### Falconiformes Cognition,

**Fig. 2** Diagram of the clear Plexiglas box used for the problem-solving test. Black dots represent the pieces of meat and the arrows indicate the movement direction necessary to open each lid. (Extracted from Biondi et al. (2010a))

first experience with the novel task, a process of learning occurred, that is, individuals behaved randomly until by trial and error the correct responses (those that allowed access to food) were performed and then repeated and improved during the next sessions. More recently, Solaro and Sarasola (2019) used the same experimental protocol and test apparatus as Biondi and collaborators (Biondi et al. 2008, 2010) to compare the problem-solving capacity between chimangos occurring in suburban and rural habitats. They found an enhanced solving performance in raptors coming from more urbanized areas, a result that was already observed in a considerable number of other bird species (reviewed by Griffin et al. 2017).

Although not belonging to the Falconiformes order, another study on raptor cognition worth mentioned belongs to Colbert-White and collaborators (2013), who investigated the ability of Harris's Hawk, *Parabuteo unicinctus* (Accipitriformes) to solve a string-pulling task, an experiment test that has been used to evaluate avian problem-solving capacity and, more specifically, insight or folk physics (Pearce 2008). This species is recognized for its complex social behavior reflected in its cooperatively hunting behavior, so the link between this attribute and their potential cognitive abilities is straightforward. In accordance with this claim, Colbert-White and collaborators found that this raptor species was able to successfully solve the string-pull task with a relatively fast time of first solution, and then enhancing their techniques with experience. Although this capacity could rely on simple operant learning mechanisms (i.e., trial-and-error learning), the evidence of this general problem-solving skills in two non-closely related raptors species highlights the need for more research on the evolution of the underlying cognitive abilities in birds of prey.

## Social Learning

Social learning can be defined as any modification of the behavior that is acquired at least to some extent, by paying attention to the behavior of

another animal or its products (Heyes 1994). Thus, social learning involves an observer (naïve) and a demonstrator, who performs the behavior that later will be reproduced in whole or part by the observer. To be classified as learning rather than facilitated behavior, the observer's performance must occur at a later time, without the influence of the demonstrator. By copying others, for example, naïve animals can learn about novel resources, the location of food and water sources, how to identify and avoid predators, and how to move safely around their environment, minimizing at the same time the cost linked to asocial or individual learning (Heyes 1994; Galef and Laland 2005). Social learning can be found in numerous taxa and behavioral domains, and theoretical works indicate that it will be advantageous mostly in changing environments where genetic change is too slow and asocial learning too costly to cope with change (Reader 2016).

Raptors have traditionally been considered as solitary predators. However, it is well known now that the majority of them show at least some degree of gregariousness, relying to varying extents on social information about feeding behavior, mate choice, nest location, and other habitat resources. For example, different types of social foraging can be found in this avian group, from true cooperative searching and hunting (e.g., pack hunting by Harris' Hawks) to opportunistic aggregations in response to high concentrations of prey (see Ellis et al. 1993). Moreover, several species of Falconiformes show communal roosting and colonial breeding behaviors (Ferguson-Lees and Christie 2001), which enhance the opportunity and adaptive value of using social information and learning from it. In spite of these characteristics, few attempts have been made to analyze the behavioral and ecological factors that determinate the probability of social learning in these predatory birds.

One of the most common documented cases in raptor behavior in which social learning is invoked is regarding the development the hunting and flight skills of in young raptors. This learning (both social and asocial), which occurs mostly during the postfledging period when parent-

offspring dependence is highest, is assumed to be of key importance in the survival of juveniles after independence (Newton 1979). In this sense, for example, adults of some raptor species are considered to have an active role in the development of flight and hunting behavior of its offspring, by training or “teaching” the young birds while hunting within view of the nest and through aerial food-passes, sometimes of live prey (e.g., Meinertzhagen 1954; Kitowski 2005). This is the case, for example, of adults of ospreys (*Pandion haliaetus*), a fish specialist species of Accipitriformes, that have been observed dropping caught fish to their offspring allowing them to dive and catch the prey, behavior that has been considered to be part of a parents’ teaching strategy, to allow their young to practice their hunting skills (Meinertzhagen 1954). However, more recent studies have suggested that this raptor species did not teach their offspring at the nest to hunt they prey, as previously thought (Howard and Hoppitt 2017). Social hunting involving siblings and parents, or only juveniles, is another example in which social learning (i.e., observational learning) has been proposed as the mechanism underlying the improvement of hunting skills in young raptors (e.g., *Falco sparverius*: Varland et al. 1991, *Circus aeruginosus*: Kitowski 2009). Nevertheless, there are also several documented cases in which young raptors were observed to carry out hunting attempts during the postfledging dependence period, without its parents or adults present (Kross and Nelson 2013; Ruaux et al. 2020 and references therein) indicating that postfledging individuals can train its foraging techniques alone, without the necessary presence of an experienced demonstrator. In all of these works, there is no certainty about the extent to which asocial and social learning are involve in the hunting behavior development of different raptors species, so there is a great need for controlled and experimental studies to determine their relative importance.

Regarding social learning about novel adaptive behaviors, only one study has been done that explore this phenomenon throughout an experimental approach. This is the case of Biondi and collaborators (2010b), who evaluated the ability

to socially acquire a novel feeding behavior in wild-caught individuals of Caracara Chimango. This is a gregarious species, with communal roosting and colonial breeding habits, also forming feeding aggregations in sporadic food sources, like carcasses and waste landfills (Ferguson-Lees and Christie 2001). Biondi and collaborators had already shown the notable capacity of innovative problem-solving in this raptor species (see previous section) and what factors determinate the individual variability in its performance. However, the innovation process also includes the spread of its product through the population, and the transmission of such innovation between generations, via social learning (Tebich et al. 2016). On these grounds, Biondi and collaborators tested whether the ability to solve a novel extractive feeding task was improved by observing the behavior of a trained demonstrator, assessing the age of both observers and demonstrators on the probability of social learning in the chimango. The authors first trained a group of chimangos (juveniles and adults) to reach the food hidden inside an opaque Plexiglas box with two lids, using the successive-approximations method. This group of trained birds was then used as demonstrators to perform the learned box opening behavior in front to an unexperienced bird (observer). Each of these observer birds was exposed to a demonstrator during several trials and then tested with the same experimental box but in isolation. The authors compared the box opening success and performance between the observer group and a control group, made up of chimangos that did not have the chance to previously observe a demonstrator opening the experimental box. Also, they recorded the opening techniques used by the observer individuals to then compare it with those shown by its demonstrators (Fig. 3). These authors found that individuals in the observer group outperformed control individuals both in solving speed and success and that this performance was maintained and/or enhanced during the subsequent session days only in the observer group. These results represent direct evidence of the capacity of this raptor species to learn a novel feeding task by observing the behavior of an

**Falconiformes Cognition, Fig. 3** Schematic drawing of the three opening techniques used by the control and observer individuals during the social learning test. (Extracted from Biondi et al. (2010b))

experienced conspecific. Also, in the observer group, juveniles opened the box faster than adult observers, which may reflect the higher persistence of juveniles during a problem-solving task and their higher propensity to rely on social clues to make a behavioral response, thus reducing the need for time-consuming and costly trial-and-error individual learning. Finally, the opening techniques used by observers did not always match the motor actions of their demonstrators. The authors suggested that some form of non-imitational social learning, such as stimulus enhancement or emulation, was probably involved.

## Conclusion

Until now, raptors are represented in an extremely low percentage of the cognitive studies performed in birds. The works presented here indicate

significant cognitive capacities of this group of predatory birds, which in part reflect their already shown relative brain size, comparable in some cases with that found in corvids. However, taking into account that this is a highly diverse group with different ecological strategies and life-styles, it would be necessary to evaluate how these characteristics influence, and are influenced by, their cognitive attributes.

Caracara locomotion; Falcon locomotion; Falconiformes flight

## Definition

Movement used by members of the family Falconidae (i.e., falcons and caracaras) to traverse their environment.

The order Falconiformes is made up of approximately 60 species of diurnal birds of prey. Clades within Falconiformes include families Falconidae (falcons, caracaras, *Polihierax*, and *Neohierax*) and Herpetotheridae (laughing falcon and forest falcons). Falconiformes are estimated to have been around for 60 million years, with extant genera ranging from 2 to 19 million years (Mindell et al. 2018). The family has a cosmopolitan distribution with the exception of central Africa, and some parts of the Arctic and Antarctica. They inhabit a range of environments, such as tundras, rainforests, and deserts. Species like peregrine falcons (*Falco peregrinus*) are found in a wide array of habitats while species like the Mauritius kestrel (*Falco punctatus*) are restricted to island habitats (Tardoff 2002).

Falcons and caracaras range in size from small to medium-sized birds. They have hooked bills, sharply curved talons, and excellent eyesight. Falcons and caracaras are carnivorous, and they feed on birds, reptiles, insects, and small mammals

such as bats. (Mikula et al. 2016). The genus *Falco* are fast-flying predators while other species, particularly the *Caracara*, are more sedentary in their feeding style (Collopy 1977).

## Flight Biomechanics in Falconinae

The main method of locomotion for the order Falconiformes is flight with some exceptions. The modes of flight include flapping, gliding, soaring, and diving. The family Falconidae consists of three recognized subfamilies, Falconinae, Polyborinae, and Herpetotherinae (Picasso and Mosto 2018), each with different flight behaviors (Mosto et al. 2018). The peregrine falcon (*Falco peregrinus*) and the merlin (*Falco columbarius*) rapidly flap their wings to locate and hunt prey. They strike their talons to kill their prey (Mosto 2016). The falcons and merlins belong to the genus *Falco*, and these birds generally require more energy expenditure to sustain such fast-flying flapping flight. A result, these species have a larger muscle mass (Siewwright and Macleod 2012), particularly the *m. pectoralis* and *m. supracoracoideus*. The larger muscle mass inherently generates a greater force that allows the birds to rapidly change the position of their wings and facilitate rotation of the wing (Bribiesca-Contreras et al. 2019). In contrast, gliding and soaring birds selectively utilize the muscles that maintain an outstretched horizontal wing position to balance two types of force: a gravitational force and an aerodynamic force generated by air flowing over the body and wings (Tucker 1998) (Fig. 1). These birds keep a varied extended wing posture depending on their speed (Bribiesca-Contreras et al. 2019). At low speeds, the gliding birds spread their wings entirely, and they decrease their wingspan as their speed increases (Tucker 1998). Soaring birds maintain or gain altitude by flying upward and accelerating air currents (Tucker 1998). Soaring flight can be static or dynamic. A static soaring bird maintains its flight by the upward velocity component of air equal to or greater than the bird's sinking speed, whereas a dynamic soaring bird utilizes changes in horizontal wind velocity component to stay aloft.

The two primary muscles of flight are the *m. pectoralis* and *m. supracoracoideus* muscles, which depress and elevate the wing, respectively (Bribiesca-Contreras et al. 2019; Tobalske 2007). Both muscles insert on the humerus (Tobalske 2007). The two main phases of flapping flight are the upstroke and downstroke (Dial et al. 1988), and it is mediated by different movements of the humerus through depression, elevation, protraction, retraction, and rotation (Picasso and Mosto 2018). The downstroke provides the majority of the propulsive force needed to generate lift and thrust, and upstroke prepares the wing for downstroke (Dial 1992; Picasso and Mosto 2018).

Geometric morphometric techniques show that variation in humeral morphology is associated with different flight speeds and flight styles. For instance, the deltoid crest is a key feature in differentiating fast and slow fliers as well as differentiating the different modes of flight. The deltoid crest serves as an attachment point for *m. deltoideus minor* and *m. pectoralis minor*. Fast-flying flapping birds require a large attachment area to the deltoid crest for the pectoral

muscles compared to the slower, soaring fliers. This increased area of attachment serves to prevent excessive muscle strain and bone breakage. Slow soaring fliers require a steady force from the pectoral muscles and require a smaller area of attachment to the deltoid crest (Sievwright and Macleod 2012).

Falcons attack prey in the air at the end of a high-speed, high-altitude dive (Tucker 1998). Peregrine falcons have been known to fly up to  $320 \text{ km h}^{-1}$  during a dive making them the fastest animal in the world (Ponitz et al. 2014a, b). The peregrine falcon beats its wings before the dive to accelerate and folds its wings close to its body to begin the dive. The closer the wings are to the body, the faster it moves as drag is decreased. There are two criteria that must be met for a bird to dive. First the bird's gliding path must be straight. Second, its wingspan must be less than 70% of its maximum length (Tucker 1998). Peregrine falcons can fine-tune their body during a dive through wing morphing which changes the shape of the wings to resemble a diamond shape. The changes in wing positioning correspond with the three phases of diving: acceleration/diving

phase, transient phase, and deceleration phase. At the beginning of the dive, the wings are close together and they gradually open up as the dive progresses (Ponitz et al. 2014a, b).

During the accelerating phase, peregrine falcons (*Falco peregrinus*) increase speed by moving the frontal portion of its wings into a cupped formation to reduce drag and increase lift. The cupped wing shape occurs when the outer edges of the wings point inward and downward to create a streamlined body shape that helps reduce drag (Ponitz et al. 2014a, b). The streamlined body shape resembles a diamond and allows the flow separation of the air during the dive to flow towards the tail rather than over the wings (Ponitz et al. 2014a, b). During the transient phase, the speed at which the falcon is traveling is constant because the drag has equalized to the constant gravitational force. The speed remains constant until the deceleration phase, which is at the end of the dive. Falcons control their speed during a dive by changing the amount of drag. However, it must be done without increasing their lift as that could result in falcon pulling out of a dive prematurely (Tucker 1998).

As the falcon nears the end of the dive, it opens its wings to slow down. This increases drag and generates lift (Ponitz et al. 2014a, b), enabling the falcon to pull out of the dive. During this time, the bird transitions from a straight flight path to a curved flight path, producing large external forces on the body amount of and wings of the bird. Due to the high amount of force placed on *F. peregrinus* during a high-speed dive and pullout, these birds require bones that are resistant to fracture (“solid bones”). Thus, *F. peregrinus* have thick-walled humeri and high bone mineral density in the humerus, radius, ulna, and sternum, allowing the falcon body to withstand forces that are three times its body weight especially during the pullout of a dive (Schmitz et al. 2018).

### Polyborinae Locomotion

Caracara have a varied foraging diet that consists of invertebrates, vertebrates, carrion, and garbage (Picasso 2018). These birds exhibit erratic and

slow flight behavior by alternating between flapping and gliding (Mosto et al. 2018). The forelimb muscles of caracaras have relatively small mass resulting in require less energy expenditure and contributing to their gliding flight pattern (Picasso and Mosto 2018). This subfamily is unusual compared to the other Falconiformes, due to the increased time spent on the ground rather than in the air. These ambulatory birds are known to have longer hindlimbs to allow them to efficiently ambulate on the ground (Mosto et al. 2018) (Fig. 1). The long hindlimbs are due to an elongation of the tarsometatarsus that serves to increase stride length making locomotion on land more energetically effective (Mosto 2016).

The musculature of the hindlimbs in Polyborinae is also distinct compared to the rest of the Falconidae. The *m. flexor cruris lateralis* is an important hip extensor that prevents hyperextension of the knee while walking and is typically absent in the rest of the species in Falconidae. The presence of this muscle means that caracaras can walk, run, and jog on land for extended periods of time (Mosto 2016). Conversely the hip extensor *m. flexor cruris medialis* is present in all species within Falconidae but is twice as big in caracaras (Mosto et al. 2018). Such an increase in size may provide additional muscular propulsion during striding locomotion. *M. fibularis longus* is an ankle joint extensor that is responsible for generating the propulsive force for the bird to lift off the ground and is found in all the species with Falconidae. However, in caracaras the muscle is larger and more developed than in other falcons (Mosto 2016). By possessing different morphological features in their limbs and muscles, these species have adapted to a more terrestrial environment.

### Falconry

Falconry is the hunting of wild animals in their natural state by means of a trained bird of prey controlled by its trainer. Falcons used are the “longwings,” including peregrine falcons, kestrels, gyrfalcons, and Saker falcons (Kenward et al. 2001). While falconry was initially

developed for purposes of subsistence hunting, today other utilitarian uses have taken advantage of the falcons' locomotor abilities, such as recreational hunting and pest control. Peregrine falcons have been used to disperse pest birds that frequently strike aircrafts, which might make for a hazardous flight situation for the aircrafts. They have also been used in dispersing pest birds that feed upon agricultural crops, which limits the produce, and thus economic continuity of farming and agriculture (Erickson et al. 1990).

Falconry is also used as a biodiversity tool to keep birds of prey healthy and improve their survival. Historically, falcons were protected by falconers preserving their nests, but more recently, decline in falcons has been observed, particularly the Saker falcon in Asia and the Peregrine falcons, in part due to pesticides such as Dichlorodiphenyltrichloroethane (DDT), and electrocution by voltage lines. Remnants of DDT accumulates in the food chain, and in addition to health consequences in the raptors, it also deregulates calcium thinning the shells of falcon eggs. As such, eggs are crushed by nesting mothers, leading to an even further decline in surviving numbers. Falconry in this context acts to reintroduce falcons to areas that have suffered severe decline, or even complete extinction, of the falcons. This is achieved by training falcons that are a few months old by experienced falconers, and that ensures that the falcons stay healthy and in good condition. Additionally, their plumage is maintained by falconers, which is vital for the locomotion of the falcon and its hunting success (Kenward 2004; Kenward and Gage 2008).

## Adaptation to Urban Environments

Peregrine falcons have been increasingly settling into urban environments, as these provide an advantage for the raptors both in terms of hunting behavior and food resources. Falcons seem to prey most often on feral pigeons, but other prey species are observed seasonally. Peregrine falcons have been noted to hunt at night near the Empire State Building in Manhattan, New York City. The

falcons are attracted to tall, well-lighted, anthropogenic structures. The platforms allow the falcons to perch at or above the level of migratory birds, especially nocturnal migrants, allowing the falcons to swoop down to hunt. The lights of these buildings act as a disorienting element to the migrants, which generally result in bird-to-skyscraper collisions annually, but for the falcons, it is advantageous, allowing for higher hunting success rates (Gahbauer et al. 2015).

## Conclusion

The order Falconiformes is made up of around 60 species of diurnal birds of prey that are colloquially known as falcons and caracaras. The falcons are fast-flying predators that attack their prey in the air while caracaras are foragers that spend much of their time on land. Falcons have many modes of flight while caracaras fly when necessary and mainly alternate between flapping and gliding modes. This difference in locomotion has led to differences in osteology and myology within the different subfamilies of the order. The peregrine falcon is known for its diving abilities, which is achieved through carefully timed shape changes its wings to achieve maximum speeds. Falconry has been used for millennia to hunt wild animals using a trained bird of prey. More recently, falconry has become largely recreational, but the birds are also used as a biodiversity tool to keep birds of prey healthy and improve their survival. Due to their global distribution, falcons, especially peregrine falcons, are common in urban environments where they have been able to establish high perches and gain easy access to prey in the night.

## Falconiformes Sensory Systems

Almut Kelber

Lund Vision Group, Department of Biology, Lund University, Lund, Sweden

### Synonyms

Hearing; Magnetoreception; Mechanosensation; Olfaction; Taste; Vision

### Definition

The order Falconiformes has evolved around 60 million years ago and comprises two families, *Herpetheridae*, the laughing falcon and forest falcons (eight species), as well as *Falconidae*, falcons, pygmy falcon, falconets, and caracaras (66 species; Mindell et al. 2018). Falconiformes occur on all continents except Antarctica, they are carnivorous birds with sharply curved talons and hooked bills and range in size from the sparrow-sized *Microhyrax* falconets to the medium-sized species of the genera *Falco* and *Caracara* (Fuchs et al. 2015).

Sensory systems allow animals to receive information on physical and chemical properties of their environment, including conspecifics, predators and food sources, and retreats. Birds have access to information from the magnetic

sense, vision, olfaction, gustation, hearing, and mechanosensitive cells associated with specialized feathers.

## Introduction

Sensory systems are adapted to the ecology and behavioral needs of animals, specifically their habitats, feeding habits, mate finding strategies, locomotion, diurnal activity range, and predator avoidance strategies. These will be introduced shortly, before turning to the sensory systems and abilities of falconiform raptors. Falconiformes inhabit a wide range of habitats, including tundras, rainforests, and deserts. While species such as the Peregrine falcon (*Falco peregrinus*) are found in many habitat types including cities, others, such as the Mauritius kestrel (*Falco punctatus*), are restricted to islands.

Being raptors, falconiforms feed on birds, reptiles, insects, and small mammals such as bats (see, for instance, Mikula et al. 2013). *Ibycter americanus* is a specialist predator of social wasp nests (McCann et al. 2015), and *Herpetotheres cachinnans* is feeding on snakes (Costa et al. 2014), but most species are more generalists. The genus *Falco* are fast-flying predators, attacking prey in the air, after a high-speed dive from high altitude. The peregrine falcon can reach speeds of up to 320 km/h during such dives, making them the fastest of all animals (Ponitz et al. 2014). Cruising speeds of falcons are slower, between 35 and 45 km/h, in several species of falcons (*F. naumanni*, *F. tinnunculus*, *F. vespertilius*, *F. subbuteo*, *F. eleonora*, *F. peregrinus*; Alerstam et al. 2007). Caracaras are opportunistic foragers that spend a lot of time walking on the ground hunting small animals like insects, but also scavenging on carcass or eating fruits and even garbage (Picasso and Mosto 2018).

Even though Falconiformes generally are diurnal, almost a third of the species can also be active in dim light or at night (see Mitkus et al. 2018 for references). Red-throated caracaras (*Daptrius americanus*) are active before sunrise and after sunset, hunting prey by walking on the ground,

and Pygmy-falcons (*Polihierax* spp.) as well as Forest-falcons (*Micrastur* spp.) hunt in dim light, under the canopy of tropical forests. Other falcons using open landscape regularly hunt on the wing migrant passerines or nocturnal seabirds, insects, or bats at crepuscular times after sunset: Eleonora falcons (*Falco eleonorae*), Sooty falcons (*F. concolor*), four species of hobby (*F. subbuteo*, *F. cuvierii*, *F. severus*, *F. longipennis*), Dickinson kestrel (*F. dickinsoni*), Bat falcon (*F. rufigularis*), Merlin (*Falco columbarius*), Peregrine falcon (*F. peregrinus*), and Lanner falcon (*F. biarmicus*). Common kestrels (*F. tinnunculus*), Lesser kestrels (*F. naumanni*), and Peregrine falcons, living in cities, which are illuminated at night, can increase their foraging time by being active at night (see Mitkus et al. 2018).

Intraspecific communication is poorly studied in Falconiformes. Little is known on acoustic communication in falconiforms, but vocalizations tend to cover a broad frequency range between 0.6 and 10 kHz, with dominant frequencies between 1 and 4 kHz (Jurisevic 1998). Sexual dimorphism, potentially indicating the use of visual signals for intraspecific communication, is only found in few falconiforms including some kestrels (*Falco* spp.; Sarasola et al. 2018). In the Chimango caracara (*Phalcoboenus chimango*), there are no plumage differences, but the adult male has pigments, vascular red coloration with the pumping of blood to the exposed skin bright yellow cere and legs, whereas the female and the juvenile of both sexes present either pinkish or bluish coloration in those areas (Sarasola et al. 2018). Skin flushing also occurs in Southern caracaras (*Caracara plancus*). In many species of falcons and kestrels, the cere of the beak and the feet are colored yellow, orange, or, more rarely, red, as in the Red-footed falcon (*Falco vespertinus*) and Amur falcon (*Falco amurensis*).

Like other birds, falcons and caracaras have well-developed senses of vision and hearing. The general belief that birds have a poor olfactory sense is in the process to be refuted, and little is generally known about mechanical senses allowing flying birds to sense air flow. The following sections will deal with these senses in detail.

## Vision

Falconiformes, as all raptors, are known for their outstanding visual abilities. Their two large lens eyes provide them with close to panoramic vision, leaving a blind sector of only slightly more than 60° behind the head (Potier et al. 2017). Of the two species studied to date, the Saker falcon had a smaller binocular field (max 37° width) than the Southern caracara (*Caracara plancus*; max 47° width).

Visual acuity, or spatial resolution of vision, has been determined in three species using behavioral experiments. The Brown falcon (*Falco berigora*), the largest studied species, was able to resolve gratings with 76 cycles/° visual angle, the smaller American kestrel (*Falco sparverius*) could resolve 40 cycles/° and the Chimango caracara (*Milvago chimango*), on average 30 cycles/° (see Potier et al. 2020b for details and additional references). Anatomical studies confirm a similar value for the Common kestrel. The high spatial resolution of falcons is supported by a high density of retinal neurons, specifically the cone photoreceptors and the retinal ganglion cells, in a small specialized part of the retina, the fovea (Potier et al. 2017). The Southern caracara has only one such specialized region of high resolution in the central retina, the central fovea. All investigated falcons, by contrast, have an additional fovea in the temporal part of the retina, which looks forward and is thought to help the birds in handling prey while the opportunistic caracaras lack the second fovea (Mitkus et al. 2017; Potier et al. 2017; Potier et al. 2020b).

Like the majority of birds, Falconiformes are well adapted to see in color using four spectral types of cone photoreceptors sensitive to violet, blue, green, and red light, with narrow spectral sensitivities (Wu et al. 2016). They also have double cones with a broader sensitivity and rod photoreceptors adapted to see well in dim light, but both these are absent from the fovea, at least in the studied species, the Peregrine falcon (Mitkus et al. 2017).

Being the fastest flyers in the animal kingdom, falcons also have the ability to see fast, they can see the flickering of a light at temporal

frequencies up to 102 Hz (in the Saker falcon) and 129 Hz (Peregrine falcon; Potier et al. 2020a), thus twice as fast as humans. Such fast vision is, however, only possible in very bright light conditions.

All the mentioned adaptations allow falcons to successfully aim for flying prey. Both the acuity and speed of vision, however, are clearly diminished in dim light (Reymond 1987; Potier et al. 2020a), again, making falconiforms best adapted to hunt during the day. However, their vision in crepuscular conditions or in a nightly illuminated city seems good enough to occasionally catch prey (see above).

## Hearing

Birds mainly use acoustic information for communication and prey and predator detection. Sounds of low frequency can propagate over long distances while high frequencies can be used for more private communication. The outer ear of birds is a tube positioned just behind and below the eye, thus making directional hearing important. Many birds thus have highly directional tympana, due to their interaural canal. Sound frequency and location of a sound source are coded in the avian auditory midbrain nucleus (nMLD). In the Brown falcon (*Falco berigora*), omnidirectional cells and hemifield cells were found (Calford et al. 1985). Unlike the barn owl, where such units have circumscribed receptive fields, falcon cells sensitive to specific stimulus locations had large receptive fields, which were restricted in azimuth but not in elevation (hemifield units). These cells could not provide an acoustic space map representing azimuth and elevation, but cells with contralateral borders found more superficially in the tissue and those with ipsilateral borders were situated deeper in the nucleus. Units in the central region of nMLD were sharply tuned to stimulus frequency, arranged in tonotopic sequences, and were omnidirectional, whereas units in the lateral region of nMLD were less frequency specific and had hemifield receptive fields in the contralateral sound field (Calford et al. 1985).

All units were most sensitive to frequencies of less than 5 kHz, and no units responded to tones above 6 kHz. The spatial properties of cells in the raptor nMLD are probably primarily determined by the directional properties imparted upon the auditory system by the interaural canal.

## Chemical Senses: Olfaction and Taste

The sense of smell – allowing for detection of chemicals from the distance – has long been neglected by researchers studying sensory biology of birds. Birds lack the vomeronasal organ known from many other vertebrates, but the olfactory system of many species is well developed, and the number of functional olfactory receptor genes generally quite high (Steiger et al. 2008).

Little is known about olfaction in Falconiformes specifically. The nostrils, positioned above the bill, are always open, and inhaled air passes through three chambers or conchae (Roper 1999). The first concha filters out small particles and warms the air, the second concha also filters the air, but the third concha is lined with olfactory epithelium, from which the olfactory receptor cells send their axons directly to the olfactory bulb. Only 63 olfactory receptor genes have been found in the Peregrine falcon and the Saker falcon, and less than half of these genes were considered to be functional (Zhan et al. 2013). This is fewer than in other birds, which can have between around 100 (in the galah, *Eolophus roseicapilla*) and more than 600 (kakapo, *Strigops Habroptila*) olfactory receptor genes (Steiger et al. 2008).

Maybe more importantly, in behavioral tests, Potier et al. (2016) have shown that, in the absence of other cues, the Southern caracara *Caracara plancus* can find food using smell exclusively. Compared to visual cues, olfactory cues did not seem to be prevalent. There is also some evidence that the foul-smelling secretion of the Great spotted cuckoo, *Clamator glandarius*, may act as an olfactory repellent for different species of falcons. Falcons refused to eat chicken meat after it was sprayed with a synthetic mixture of juvenile cuckoo secretions (Röder et al. 2014). Almost no information on chemical

communication or the use of olfactory cues for navigation in raptors is available.

The sense of taste – allowing for the detection and discrimination of chemical and nutrients in food – is even less studied in falconiform birds. The taste buds of birds are distributed in the oral cavity, more frequent on the palate, the lower mandible, and the pharyngeal floor than the tongue. They are not associated with papillae and are connected with the surface by a taste canal (Erdoğan and Iwasaki 2014; Rowland et al. 2015). Genomic studies on the peregrine falcon have revealed that falconiforms, like other birds, have lost one of the three G-protein coupled taste receptors that mediate the perception of umami and sweet resulting in a loss to sense sugars (Baldwin et al. 2014). They have two functional genes for bitter receptors, compared to three in the common ancestor of birds (Wang and Zhao 2015). Sour and salt receptors are presumed to be ion channels rather than G-protein-coupled receptors, and present in all birds including falconiforms.

### Somatic and Magnetic Senses

Like other birds, falcons have additional senses, but these are barely studied (Martin 2017). The somatosensory system includes receptors distributed over the body to allow the birds to detect, thermal, noxious, and mechanic stimuli such as vibration, pressure, or air flow (Gottschaldt 1985). Two types of somatosensory receptors are found in the dermis: Herbst (lamellar) corpuscles sensitive to vibration and Grandry corpuscles that respond to rapidly acting movement (Gottschaldt 1985). They are important for behavioral control for flight, feeding, and other tasks but have not been studied in Falconiformes specifically. Of specific interest are rictal bristles that, similar to the whiskers of mammals, may have various functions including protection of the eyes from airborne particles, preventing the soiling of facial feathers during feeding or aiding in navigation (Delauney et al. 2020).

While it has been proven for a number of bird groups including passerines and pigeons, the ability to sense the magnetic field of the earth has not been studied in falcons. It is thus possible but not

sure that falcons can use this modality to navigate in their surroundings. The anatomical and histological basis of the magnetic sense has not been understood for birds yet even though hypotheses exist (Wiltshko and Wiltshko 2019).

### Conclusions

Falconiformes comprise falcons, the fastest-flying animals on the globe, which have excellent visual abilities with high spatial and temporal resolution. Other falconiforms, such as caracaras, predominantly move more slowly, but share many sensory traits. While falconiform vision has been studied to some degree, other sensory modalities are still barely understood in these fascinating birds.

The feeling that an item has been recently experienced without clear recollection of other contextual information about the experience.

## Introduction

In everyday life, the word familiarity gets used in many ways. For instance, one might discuss their familiarity with animal cognition, their friend Susan, or the name Navalny. One is referring to knowledge about a topic, the second their relationship with an individual, and the last their sense

of a previous encounter. These are very different cognitive experiences with the only overlap being an involvement of previous experience. Unfortunately, the use of the term familiarity in animal cognition is similarly broad. It is used to discuss the effects of previous experience on perception (e.g., Talbot et al. 2015), social behaviors (e.g., Wickberg et al. 2014), categorization (e.g., Stephen et al. 2013), and memory judgments (e.g., Basile and Hampton 2013).

Unlike everyday life, in cognitive memory research, the term familiarity has a specific definition. Familiarity is the “feeling” that an item has been recently experienced without clear recollection of other contextual information about the experience. It is a noncontextualized “sense” of memory. Familiarity is contrasted with recollection, the specific memory of an item tied to other information about the context. In this case, the memory not only includes the item but also associated information such as time or place. Familiarity can also be contrasted with fluency. Fluency is the ease of processing an item, and fluency is often increased by recent experience. Some theories assume that fluency is the primary cue underlying feelings of familiarity. However, even when this relationship is assumed, the definitions of fluency and familiarity are not interchangeable, and there is clear evidence that perceptual fluency can happen without an accompanying sense of familiarity (for review see, Yonelinas 2002).

## Theories of Familiarity

There are two primary classes of theories to explain the experiences of familiarity and recollection. The first class assumes that feelings of familiarity and recollection are tapping different cognitive processes requiring different areas of the brain that can be dissociated and understood independently. There are a number of different dual process theories that vary substantially in their assumptions about the underlying mechanisms of familiarity. However, they all assume that familiarity is qualitatively distinct from recollection. They also assume that familiarity is a

faster and more automatic process relying on different parts of the medial temporal lobes than recollection. The most common neurophysiological assumption is that hippocampal involvement is necessary for recollection, while parahippocampal cortex mediates feelings of familiarity (for review, see Yonelinas 2002).

The other class of theories assumes that differences in familiarity and recollection are explained by differences along a continuum such as memory strength. These single process theories also tend to assume differential involvement of the parahippocampal cortex and the hippocampus in judgments of familiarity and recollection, but they assume these differences reflect the requirement for hippocampal input for “stronger” memories (for review, see Yonelinas 2002). Because the differences in the theories’ predictions about brain-area involvement are subtle, the search for appropriate animal models of familiarity and recollection has been considered vital to distinguishing between them.

### Tasks Used to Examine Familiarity in Nonhuman Animals

In animal cognition, the delayed match to sample (DMS) and delayed non-match to sample (DNMS) are generally used to assess memory. Though specific methodologies can vary across species, the basic idea behind DMS and DNMS is that if an animal behaves differently toward items based on previous experience, then they are expressing memory. These tasks are akin to recognition memory tasks in humans because the items are present. Comparative researchers have usually assumed that performance on these tasks reflects the animal’s sense of familiarity with the items, and they have been used to try to determine the role of different parts of the medial temporal lobes in familiarity (e.g., Hölscher et al. 2003). However, in human research, recognition memory clearly involves both familiarity and recollection (for review, see Yonelinas 2002). Therefore, this assumption about nonhumans may not be correct. In human research, task-dissociation procedures and process estimation techniques have been used

to try to determine the relative contributions of familiarity and recollection to recognition memory. Some of these techniques have been applied in comparative studies as well.

*Task-Dissociation Procedures with Nonhuman Animals.* In the human literature, there is an assumption that recall performance always reflects recollection. However, successful recognition could reflect a sense of familiarity or a recollective experience. Therefore, many researchers have used the subtraction of recalled items from recognized items as a measure of pure familiarity.

Recall tasks are relatively rare in the animal cognition literature because designing tasks that allow animals to behaviorally show memory for items that are not present is difficult. However, to dissociate recall and recognition, researchers developed a paradigm where rats (*Rattus norvegicus*) learned to associate two objects with particular locations in a maze in different contexts (e.g., Eacott and Easton 2007). They were then habituated to one object and released into the context-dependent maze. The object location they went to first and the time spent exploring each object was measured. They hypothesized that if the rat recalled the objects associated with the context-dependent locations, they would go to the non-habituated object first, and if they recognized the habituated object, they would spend less time exploring it. With these measures of recall and recognition, the authors explored the involvement of different areas of the medial temporal lobes in the different measures.

Another task-dissociation method relies on the assumption that recollection is necessary in associative recognition memory tests. In contrast, familiarity, because it reflects memory for items untethered from context, is less useful in these tests. Thus, tests of associative recognition have been used as an index of pure recollection. As with comparisons of recall and recognition tasks, a subtraction of associative recognition from item recognition is used to measure familiarity. An advantage of the item/associative method over the recall/recognition method is that the test cues and required responses are more similar to each other (for review, see Yonelinas 2002).

Cross et al. (2013) used this item/associative recognition task dissociation to determine the role of different brain regions in recollection and familiarity. They measured the rat's ability to perform multiple tasks. One was a DNMS task testing recognition for experienced objects. One was a DMS task where the rat chose previously experienced locations. In a third task, they tested whether rats could distinguish objects that retained their place in an array compared to those that had switched, testing recognition for item-place associations. They found different regions involved in the association task compared to the object or location tasks.

Because familiarity is assumed to be faster than recollection, response speed should be useful for separating the contribution of familiarity and recollection. Faster responses should reflect familiarity and slower responses recollection. Basile and Hampton (2013) tested this speed assumption with rhesus macaques (*Macaca mulatta*) by examining the types of errors made at different latencies. They split the monkeys' responses into three latency categories (fast, medium, slow) and examined the errors. At fast latencies, most of the errors were false alarms to familiar lures, but at medium latencies these errors were greatly reduced. The authors concluded that this pattern reflected familiarity-mediated fast responses and recollection-mediated medium responses. At long latencies, monkeys performed at chance.

*Process Estimation Procedures.* Each of the task-dissociation methods makes assumptions about the nature of familiarity and recollection, and their general limitation is their imprecise estimates of familiarity and/or recollection. Though subtraction or time cutoff methods may give an approximation of how many items are familiar, there is always likely to be some items that are incorrectly categorized. To develop more precise measures, process estimation techniques were designed to mathematically distinguish familiarity from recollection.

Process estimation procedures arose in research with humans where complex verbal instructions and verbal reports are ubiquitous. Because of this, the most common procedures like remember/know judgments (after

recognition, the participant classifies the item as something they remember from the learning context or they just know) and process dissociation procedures (compares item recognition to the ability to exclude items on the basis of a contextual cue) are simply not possible with nonhuman animals.

However, there is one process estimation technique that has been adapted with nonhuman animals. Receiver operating characteristic (ROC) analyses assume that measuring the effect of varying response criterion on hits and false alarms can allow estimations of familiarity and recollection's contribution to memory. In human research, varying response criterion is usually measured by confidence ratings. This method is difficult with nonhumans. However, ROC analyses can also be used when response criteria (willingness to call something old) are manipulated by instructions or payoff ratios (for review, see Yonelinas 2002).

Fortin et al. (2004) examined ROC curves for rats' odor memory manipulating difficulty and payoff ratio to produce varying response criteria. They found that rats showed the classic ROC curved pattern assumed to measure separate contributions of familiarity and recollection. They also found that rats with ablated hippocampi did not show these bi-process curves.

Wu et al. (2020) combined the speeded response method used by Basile and Hampton (2013) and ROC analyses to compare human and macaque familiarity and recollection measures in the speeded response paradigm. They found that both species had the same fast and slow error patterns, and both showed ROCs consistent with familiarity-driven fast responses and recollection-driven slower responses. They concluded that the simpler speeded response methodology was adequate for separating the contributions of recollection and familiarity in nonhumans.

## Conclusions

In human research, the term familiarity has a precise definition based on the "sense" of previous experience that is not concretely tied to context.

Without language to self-report this “feeling,” it can be difficult for animal cognition researchers to disentangle familiarity from recollection or fluency. However, this ability is vital both for understanding similarities and differences between human and nonhuman memory and for adequate animal models of the role of different brain regions.

Creative research using task-dissociation methods and ROC curve process estimates with rats and monkeys (e.g., Basile and Hampton 2013; Cross et al. 2013; Eacott and Easton 2007; Fortin et al. 2004; Wu et al. 2020) have helped to bridge this divide. These methods have substantially contributed to understanding mammalian familiarity processes and their neural underpinnings. Hopefully, future research will extend these methodologies to other vertebrates to explore the evolutionary trajectory of memory processes.

## Introduction

Categorization is a crucial skill that allows animals to manage their environment. Inaccurate categorization would be detrimental to the life of the animal. A vervet monkey must decide to alert their troop of an approaching bird. Is this a safe bird?

A categorization error would result in a poor outcome for the vervets. The decision must be made quickly, and there is little room for error. Unfortunately for the vervet, different species of predator birds, for instance, eagles and hawks, do not look exactly alike. Even eagles of the same species will not be identical to each other, though they share definite similarities. Many of the world's natural categories (like predatory birds) follow a family resemblance category structure (e.g., Rosch & Mervis, 1975). Family resemblance category members share an overall similarity, but no criterial attributes define all members of the category. In other words, members of the category tend to share several features with other members of the category, but there is not necessarily a single feature common to all category members. Therefore, when trying to classify these family resemblance categories, it would make sense for the vervet to make its decision by comparing the bird's overall similarity to either their representation of a typical predatory bird or the other examples of predators that they have experienced.

## Prototype Versus Exemplar Strategies of Classification

The two primary theories of how animals are able to classify family resemblance categories are the prototype and exemplar comparison theories. Prototype comparison theory hypothesizes that we average our experiences with category members (exemplars) into a single schema or prototype. We can then make categorization judgments by comparing the similarity of a new object to the prototype. In prototype comparison theory, the prototype is centrally located in a cloud of similarity, and members of varying similarity lie around the prototype. Those members most similar to the prototype will lie more closely to it in psychological space. However, the exemplars do not fall in a straight line leading away from the prototype, because the exemplars themselves can vary in similarity to each other. Instead, the exemplars form a cloud of similarity around the prototype (Smith, 2002). Figure 1 shows the prototype (P) in the center of this cloud, as it is the most representative of the category. Exemplars (E) can

### Approaching A Category System

then fall at varying distances on any side of the prototype. Two exemplars may be equally similar to the prototype, but they are perceptually very different from one another as the psychological space can have many dimensions, leaving them to fall equal distances away from the prototype but far from each other.

On the other hand, exemplar theory suggests people categorize a novel object by comparing similarity to the memory representations of *all* previous exemplars from each relevant category and then summing that similarity to decide membership (e.g., Nosofsky, 1987). Therefore, no single member is more representative of the category than the next.

Examining Family Resemblance Category Learning

Family resemblance category learning is often tested by using polymorphous categories or prototype distortion tasks. In polymorphous categories, several stimulus features are partially informative about category membership, but no single feature is present in all members (Couchman et al., 2010). Table 1 presents an example of two, binary-feature polymorphous categories, with the first line representing the best example of the category, the prototype, and the following five lines representing potential exemplars of that category. Each dimension corresponds to types of features with 0 and

1 corresponding to the value on these dimensions. D<sub>1</sub> could represent shape, in which 0 might correspond to circle and 1 to square. D<sub>2</sub> could represent color, in which 0 corresponds to blue and 1 corresponds to yellow. Looking at within-category similarity of the family resemblance categories, all category members share three features with each other and four features with the prototype. Looking at between-category similarity, members from different categories do not share more than one feature with the opposing category’s prototype.

Prototype distortion tasks create exemplars along a distortion continuum by *randomly* distorting the category prototype to controlled degrees instead of exchanging different specific features (Posner & Keele, 1968). As with polymorphous categories, no single feature is fully informative of category membership, but rather overall similarity decides category membership. The most common example consists of dot patterns, often connected by lines to create polygon shapes (see Fig. 2). Category members are created from an initial prototype dot pattern that can then be distorted spatially to have varying degrees of similarity. Often the category members are then

mixed with random shapes, and the participant must decide if the shape belongs to the category or not. Figure 2 presents a prototype, low-level distortions, high-level distortions, and random shapes.

Prototype and exemplar comparison theories each have their own predictions for how participants will perform in this task. These predictions can be tested using formal modeling (Fig. 3). Prototype comparison emphasizes a strong resonance to the prototype, so it will be endorsed into the category at maximally high levels (Smith, 2002). Exemplar theory does not predict this, because the prototype is being compared to a bunch of exemplars that may be far away from it in psychological space.

### Evidence for Prototype Comparison in Family Resemblance Category Learning

Prototype and exemplar comparison in family resemblance category learning have been studied in several animal species. The majority of research has been with rhesus macaques and humans. Studies with rhesus macaques (*Macaca mulatta*) have consistently shown that they have

strong preferences for prototype comparison. For example, in a prototype distortion task, the macaques had nearly perfect performance with the prototype, and when the data were fit using a standard prototype and exemplar model (P, E symbols in Fig. 3), the exemplar model was a poor predictor of performance (Smith et al., 2008). However, the prototype model (P symbols) fit so well that it became nearly impossible to see the symbols in the figure because they overlapped so closely the macaques' endorsements (circle symbols).

In another study, Smith et al. (2010) tested macaques in a prototype-exception task to see whether they would continue to assume a family resemblance category structure even when feedback directly signaled otherwise. If the macaques learned categories by abstracting and comparing to a prototype, they would be unable to learn exceptional category members. The researchers created eight low-level distortions from two prototypes. Six of these distortions were then kept together to constitute a prototype-based family of exemplars, and then two of the distortions produced from each prototype were crisscrossed into the opposing category. This produced two, eight-exemplar categories containing six typical

exemplars and two exceptions that could have been a typical exemplar of the other category (Fig. 4). If macaques assume family resemblance categories, then they should respond B to the exceptions on the left and A to the exceptions on the right. The macaques performed below chance with the exception items for thousands of trials. The macaques showed minimal capacity to memorize and respond appropriately to exception items even when there were only four items to memorize. However, after thousands of trials, two of the three macaques were partially able to learn the exceptions. The rhesus macaques clearly defaulted to a family resemblance assumption, and they found it difficult to learn items inconsistent with this assumption. They kept this approach, in direct opposition to the feedback, for thousands of trials.

One study with baboons (*Papio papio*) has examined their family resemblance category learning. The baboons were tested to see if they would discriminate prototypes of polymorphous categories more accurately than less typical exemplars (Dépy et al., 1997). Their performance with the prototypes was significantly greater than with novel non-prototype stimuli.

Research with pigeons (*Columba livia*) has shown similar results. Cook and Smith (2006) examined family resemblance category learning in pigeons also using a prototype-exception task. Results showed that pigeons had difficulty learning to correctly categorize the exception items, just as the macaques did. Formal modeling confirmed that pigeons' data were fit poorly by an exemplar model. Similarly to the macaques, the pigeons made a transition to exemplar memorization late in learning. Eventually, exception performance improved, and the exemplar model fit well. This transition suggests some residual capacity to finally learn/memorize exceptional items. Research using polymorphous categories has also supported the idea that pigeons use prototype comparison to learn family resemblance categories (Jitsumori, 1996).

While prototype comparison has not been directly studied in rats, Vermaercke et al. (2014) incidentally found evidence of rats using a prototype comparison strategy in a visual water-maze task using rule-based and information-integration categories. The performance of rats was consistent with a nondimensional, similarity-based categorization strategy. They found that the more

distant from the trained prototype, the worse the performance, supporting a family resemblance category structure assumption and a prototype comparison strategy.

## Conclusion

The research suggests that animals may default to a prototype comparison strategy rather than an exemplar comparison strategy for categorizing new objects. This indicates that animals assume categories are based on overall similarity or a family resemblance structure. From an evolutionary standpoint, prototype comparison may be the most efficient strategy, as one only needs to store a single memory representation as opposed to many, and it could allow for faster comparison as there is only one comparison to be made. Because family resemblance categories are common in nature (Rosch & Mervis, 1975), it makes sense that cognitive evolution might naturally move animals toward a strategy that allows them to easily and quickly learn these family resemblance category structures.

## Farrowing Crate

R. Cyril Roy<sup>1</sup> and Yolande M. Seddon<sup>2</sup>

<sup>1</sup>Prairie Swine Centre, University of Saskatchewan, Saskatoon, Canada

<sup>2</sup>Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Canada

Farrowing crates are metal stalls in which sows are typically housed from a few days before parturition until weaning (21–28 days). In the 1960s,

when intensive farming was considered as the way to improve pork production, farrowing crates were developed (Robertson et al. 1966). This was also in response to genetic improvements in pig production leading to sows being larger in size, producing more piglets per litter, and increasing the risk of piglets being crushed. Farmers and researchers reported a reduction in crushing of the piglets by the sow following adoption of farrowing crates when compared to farrowing pens (Blackshaw et al. 1994). Apart from increasing productivity, farrowing crates also helped management of the sow and her litter during routine husbandry activities such as castration of piglets and giving iron injections to piglets enabling them to be performed in a safe manner. Farrowing crates confine the sow to one place, and thus her dung is deposited in one area, at the back of the crate. This helps to keep the pen clean and increases pen hygiene for the piglets.

A standard farrowing crate provides a space allowance of around  $2.2 \text{ m} \times 0.60 \text{ m}$  (7.2 ft by 2 ft) for the sow. However, there are small size variations between manufacturers. Initial designs were made with minimal space allowance for sow along with additional pen space to contain the litter of piglets (Fig. 1). As Fig. 1 illustrates, farrowing crate “footprint” includes the pen space available for the piglets, apart from the metal crate for the sow. Therefore, the total space allowance is around  $2.3 \text{ m} \times 1.8 \text{ m}$ . Modern crate designs offer the ability to increase the width of the crate, to accommodate large sows, and facilitate lying postures (Fig. 2). Standard farrowing crates do not allow sows to turn around and limit the sow’s interaction with her piglets (Harris and Gonyou 1998). This restriction of movement at a time when sows are highly motivated to perform nesting behavior (Jensen et al. 1993) has been an ethical debate for some time now. Sniffing and nose-to-nose contact between sow and piglets are common in unrestrained conditions (Watson and Bertram 1983). Standard farrowing crates prevent turning, inspection, and reduce sow-initiated nose-to-nose contact (Blackshaw and Hagelsø 1990).

Whilst the advantages of farrowing crates were based on financial benefits and ease of animal management, the disadvantages surrounds welfare

**Farrowing Crate, Fig. 1** Farrowing crate design developed by Canada Plan Service, Saskatchewan, Ministry of Agriculture Draftsman: Don Sproule in 1976

**Farrowing Crate, Fig. 2** A well-designed farrowing crate which can be adjusted to increase the space allowance for the sow by widening one side of the wall of the crate (photo credit: Karunasena Bandarlage, Prairie Swine Centre)

concern for the sow. In many countries with a developed economy, there is an increasing consumer pressure for the farming sector to adopt methods that do not involve animal confinement systems. Consequently, in the pig farming sector, there is ongoing discussion surrounding farrowing crate use and the behavioral restrictions they bring. Identifying whether viable alternatives can be found that improve sow welfare, yet continue to protect piglet welfare and farmer safety is a goal. As new housing provisions are developed to better accommodate the natural behavior of the sow, any such system also needs to protect the piglets from being crushed (Baxter et al. 2011). Any farrowing

housing system adopted without careful consideration for piglet mortality will have obvious negative welfare consequence for the piglets (Baxter et al. 2012) and will likely also not be economically viable in the long run as a result.

Currently there are efforts to improve the design of the farrowing crate. In many European countries there is increased interest in free farrowing pens (the sow is loose during farrowing and lactation). Some of the different types developed in Europe are PigSAFE (Piglet and Sow Alternative Farrowing Environment), the Danish designed Free Farrower, FAT systems, comfort pen designed by Norwegian University of Life Sciences and WelCon (Welfare for animals and convenience for farmers) designed by Institute of organic farming and farm animal biodiversity, Austria. ([www.freefarrowing.org](http://www.freefarrowing.org)) In North America, some certification programs such “Certified Humane” are promoting the discontinuation of farrowing crates ([www.certifiedhumane.org/farrowing-systems/](http://www.certifiedhumane.org/farrowing-systems/)).

## Fear Response

Prescilla John

United States Army, New York, NY, USA

The conditioning of emotional responses has been a major area of focus by Pavlovian conditioning researchers (Fent and Fanslow 1999; Leaf and Muller 1965). Pavlovian conditioning simply refers to a form of associative learning in which

a biologically relevant or unconditioned stimulus (US) is paired with a previously neutral or conditioned stimulus to produce a conditioned response. This area of research preceded studies by Watson and Rayner (1920) who studied infants through the use of Pavlovian or classical conditioning. The researchers conditioned a fear response in a 9-month-old infant named Albert through the use of a white laboratory rat which first served as a neutral stimulus (NS) or unconditioned stimulus. Albert was first exposed to a variety of stimuli, but it appeared that there was hardly anything that he was afraid of. Watson and Rayner found that Albert had a startle response when he heard the noise of the steel bar being hit by a hammer. The loud noise of the hammer was used as an unconditioned stimulus (US), while the white rat, which was first a neutral stimulus, became the conditioned stimulus (CS) after successful conditioning. During the Pavlovian conditioning trials, Albert was exposed to the white rat, followed by the striking of the steel bar. Although Albert reached out to touch the rat at first showing no fear, after about a few conditioning trials, he became reluctant to do so. Eventually Albert displayed a conditioned emotional response of crying, whimpering, and leaning as far away from the rat as he could or even attempting to escape by crawling away.

Watson and Rayner's (1920) work on Pavlovian conditioning with Albert provided a foundation for future studies in this area. Research interest in how fear and anxiety is acquired, what the neural mechanisms of fear are, and how fear is reduced through pharmacological and behavioral treatments have been intriguing topics in this area of research (Charney and Deutch 1996; Craske et al. 2014). However, many of these questions cannot be fully explained through the sole use of human participants. In studies that model fear in animals, the aversive stimulus used is a brief shock (Fendt and Fanselow 1999). The reason that shock is used is because it can be easily regulated and calibrated to cause no harm. It serves as an aversive and unconditioned stimulus because it is both alarming and novel to the animal. While humans such as Albert show fear through crying and whimpering, rats show their fear by freezing.

## Freezing as a Fear Response

Freezing is a species typical defensive response to fear among many species, because lack of motion reduces the probability of being detected by predators (Carlson 2010; Domjan 2010). The magnitude of the conditioned response to freeze has served as a measure of conditioned fear in neurobiological studies of fear (Fendt and Fanselow 1999). Two indirect measures of freezing used by researchers have been conditioned suppression and conditioned emotional response procedures (Leaf and Muller 1965). In the conditioned suppression, the measured behavior is licking a drinking spout that contains water in an experimental chamber. When a fear conditioned stimulus such as a tone is introduced, the animal's licking behavior becomes suppressed (Leaf and Muller 1965; Urcelay and Miller 2008).

On the other hand, the conditioned emotional response is a classically conditioned response that occurs when a neutral stimulus is followed by an aversive stimulus (Annau and Kamin 1961). In the conditioned emotional response procedure, rats learn to press a lever for a reward of food in an experimental chamber. The lever pressing much like the licking behavior in the conditioned suppression task serves as the baseline for the measurement of fear. Fear conditioning, which consists of a tone or a light paired with a brief shock, is introduced only after rats have become accustomed to lever pressing. As they acquire the conditioned fear, the lever pressing becomes suppressed. The conditioned suppression procedure has also been adapted for research with humans, in which the behavioral baseline has been provided through video games (Arcediano et al. 1996; Nelson and Carmen Sanjuan 2006).

## Fight, Flight, or Freezing Response

The fight or flight response, also referred to as the fight, flight, or freezing response, is a physiological reaction to a perceived environmental threat (Leaton 1976; Seyle 1936). This response was coined by Walter Bradford Canon, who explained how animals react to threats through an activation

of their sympathetic nervous systems, which then primes the animal to either fight, escape, or freeze during a potentially harmful event or attack. The sympathetic nervous system helps the body prepare for fight or flight by releasing adrenaline, increasing heart rates and breathing rates, dilating pupils, increasing blood supply to muscles, and enhancing the organism's reflexes. If the perceived threat is intense enough, it can activate a freezing response, which is what happens in conditioned analgesia.

Conditioned analgesia is a way of inducing a fear response such as freezing. Research by MacLennan et al. (2013) found evidence of greater conditioned analgesia in rats as a result of re-exposure to initial shock conditions following test than those who were not re-exposed to the initial shock environment prior to testing. This response is referred to as the first stage of a general adaption syndrome, which is responsible for the regulation of stress responses among human and nonhuman animals (Seyle 1936).

## The Role of the Amygdala

The fight or flight response is initiated in the amygdala, which is an integrative center in the brain for emotional processing (Gazzaniga et al. 2014; Goldstein 2010; Seyle 1936). Emotional responses involve consolidative components of behavioral, autonomic, and hormonal processes, which are controlled by the amygdala. The amygdala is able to detect fear and assist in preparing for emergency events. This brain region can process sensory information and encourage a behavioral response before the information is processed by other areas of the brain. Therefore, the identification of what startled an organism often occurs post the fight or flight reaction. While the amygdala plays a key role in emotional reactions, there are other brain regions that provide pathways to the amygdala. The hippocampus is the area of the brain associated with memory and provides the amygdala with contextual information. Stimuli that have triggered emotional reactions in the past are likely to initiate a heightened sensitivity to the present situation. Emotionally significant stimuli

based on the organism's past experiences are more likely to intensify the fight or flight response.

## Startle Response

The startle response, also known as the startle reflex, is a part of an organism's unconscious response to an abrupt or threatening stimulus such as a sudden noise or sharp movement (Fendt and Fanslow 1999). This response consists of a sudden jump, tensing of upper muscles (e.g., back and neck), and eye blinking; it is evident across species. Much like the fight or flight response, the startle reflex is activated by the sympathetic nervous system. This reaction has been studied mainly due to its pivotal role in fear responses and defensive behaviors. It can be measured by placing an organism on a surface that measures sudden movements (Leaton 1976). Studies on the fear response have helped to bridge gaps in knowledge on the neurobiology of fear and the understanding of which pharmacological treatments are most effective for anxiety as well as trauma and stressor-related disorders (Charney and Deutch 1996; Craske et al. 2014).

## Conclusion

Organisms can display a multitude of reactions to fear, with freezing being one of the most common species typical responses (Fendt and Fanslow 1999; Leaf and Muller 1965; MacLennan et al. 2013; Seyle 1936). Freezing has been studied by researchers through conditioned suppression and conditioned emotional response procedures in which researchers were able to suppress a behavior by inducing fear in the animal. Other responses to fear include the fight or flight response and the startle response. The fight or flight response is a physiological reaction to a perceived or real environmental threat. This response activates systems such as the sympathetic nervous system and is processed through the amygdala or the brain's emotional processing center. On the other hand the startle reflex differs from the other two responses to fear in that it occurs unconsciously

in response to an unexpected or threatening stimulus in the environment. The organism displays a hyperarousal or startle reflex reaction where they jump and tense the muscles at the upper part of the body. Other physiological reactions that occur at this time are pupil dilation and increased heart rate to name a few. Fear reactions among animals can vary depending on how the fear was acquired and whether or not it is expected.

## Feather Damaging Behavior (FDB)

- [Feather-Plucking](#)

## Feather Picking

- [Feather-Plucking](#)

## Feather-Plucking

Rachel Baumgardner  
Michigan State University, Lansing, MI, USA

## Synonyms

[Feather damaging behavior \(FDB\)](#); [Feather picking](#); [Pterotillomania](#)

## Definition

A maladaptive, self-mutilating behavior involving excessive plucking, chewing, fraying, and/or biting resulting in feather loss or damage.

## Introduction

Naturally, birds are driven to preen (groom feathers through beak) to remove dust, dirt, and foreign objects and reset feather position. Parrots and exotic birds also have an uropygial gland (a.k.a. “preen gland”) near the base of their tail that secretes oil onto the skin surface to protect feather structure and skin health; preening allows the oil to spread from the tail to the rest of the body (Encyclopaedia Britannica 2017).

Feather damaging behaviors occur in other birds, such as feather pecking in commercial poultry. Feather-plucking occurs mainly in pet African grey parrots (*Psittacus erithacus*); however, it can occur in other captive birds, like ostriches, conures, *Amazona* spp. parrots, cockatoos, and more. It is similar to trichotillomania in humans.

Feather-plucking begins when the bird reaches sexual maturity and is rarely observed in the wild. Prevalence in pet birds ranges from 1.3% to 17.5% depending on if the bird was raised by other birds or hand-raised by humans. Most affected areas are areas easily accessible by the beak, including the chest, rump, and under wing regions. Denuded birds risk infection, hypothermia, or hemorrhage, if the blood feathers are plucked (Grindlinger 1991).

## Feather Pecking

Not to be confused with the self-mutilation behavior in pet birds, commercial poultry exhibit redirected foraging behavior involving pulling or removing conspecific's feathers. Feather pecking is detrimental to birds and economically significant to poultry producers, as it leads to increased mortality if it escalates to cannibalism.

## Behavioral Causes

Inadequate diet, environmental stimuli, and early weaning are thought to attribute to feather-plucking (Costa et al. 2016). Feather-plucking may be a coping strategy for negative affective states like stress or boredom. Unable to properly cope with its environment, the bird

develops the maladaptive behavior of feather-plucking to reduce anxiety, even if the outcome is nonproductive. Birds that feather-pluck often have three times the cortisol levels of non-feather-plucking birds, indicating high levels of stress.

Pet parrots are more frequently hand-reared by the handler or breeder, resulting in birds that imprint on humans and are socially dependent on them. It is not clear whether any one method of hand-rearing results in less negative behaviors; however, all hand-rearing is associated with aggressiveness, feather-plucking, and stereotypies. The age of removal from the nest is inversely correlated with stereotypical behavior.

Feather-plucking is more heritable than in other stereotypies, and birds susceptible to stressful situations (i.e., in view of a constantly opening door) are more likely to develop severe feather-plucking (Garner et al. 2006).

## Treatments

Clomipramine has been shown to improve feather-plucking behaviors in placebo-controlled double-blinded studies (Seibert et al. 2004). This treatment is not completely effective, and severely affected birds often will not respond to treatment.

Mechanical prevention (i.e., collars, physical restraint devices) is not recommended as a lone treatment, as it is considered inhumane. Punishment for the behavior often leads to increased or exaggerated behavior caused by stress and fear of being punished (Jenkins 2001).

Early treatment and prevention remains the best method. Providing sufficient environmental enrichment and introducing novel enrichment to the cage environment can increase meaningful activity and allow the bird to perform normal activities such as chewing, foraging, nesting, and socializing.

<sup>4</sup>Department of Biomedical Engineering, Ben-Gurion University of the Negev, Beer-Sheva, Israel

## Synonyms

Pop-out; Saliency; Vision; Visual attention; Visual search

## Definition

Feature integration theory models how attention is guided, for example, when the visual field needs

to be searched for a particular target. At its foundation, feature integration theory first employs separate but parallel, preattentive, and unconscious registration of basic visual features, and later on their integration to conscious controlled perception based on a master map of retinal locations. Attention can be guided (to facilitate object detection, for example) during either phase depending on the visual properties of the target compared to other items in the stimulus, a process that allows either fast pop-out of the target or its detection via a slower serial attentional deployment process. Conceived originally for human vision, there are many ecological reasons, and now ample evidence, to support the argument that feature integration theory is universal and relevant to many animal species too.

## Introduction

Visual attention is one of our fundamental behavioral features. As seeing creatures, humans continuously scan the visual world around us and focus our visual attention on important visual objects. From searching for our friends in a crowd to looking for a car key in a drawer, from seeking a ripe fruit on a tree to looking for a foe in a computer game, such visual search tasks often (but not always) require much visual attention. But clearly, this visual behavior cannot be unique just to humans, as most nonhuman species could benefit tremendously from guided attention for survival, including mating, hunting, navigation, and predator avoidance. How visual attention is guided also in nonhumans species is thus crucially important and can inform us a great deal about universal behavioral principles and information-processing strategies across the animal kingdom.

## Feature Integration Theory in Humans

Introduced by Treisman and Gelade in the early 1980s (Treisman and Gelade 1980), Feature Integration Theory is one of the most influential theories that accounts guided attention. According to this theory, visual stimuli are processed in two

consecutive stages. First, the visual system processes the visual stimulus to yield separate spatial maps of the distribution of basic visual features (such as color, orientation, motion, etc.). This first stage is called *preattentive* since it is performed before attention is deployed and before the organism becomes conscious of what it is looking at. The second stage is termed the *attentive* stage where the organism focuses its attention on a certain object or location in the visual field. This occurs within a master map of stimulus locations where features have been represented after processing of the individual maps from the first phase. After attention selects a certain location to focus on, the individual features at that location are integrated to facilitate the conscious perception of the relevant visual information.

Testing Feature Integration Theory and its applicability is typically done using controlled visual search experiments. In a typical experiment, subjects are asked to detect the presence or absence of a target in a display as quickly and as accurately as they can, where the target is characterized by a certain combination of features that distinguish it from other nontarget distracting items around it. Using this methodology, and

under the classic framework of Feature Integration Theory, Treisman and her associates characterized two distinct visual search modes, which they dubbed *parallel* and *serial* (Treisman and Gormican 1988; Treisman and Gelade 1980).

The parallel search mode occurs in the preattentive stage where certain visual features are processed immediately throughout the entire visual field and in a massively parallel fashion. If any of these features uniquely characterizes the target, the latter pops out to complete the search. This automatic process is reflected in a reaction time that is relatively unaffected by the number of items (a.k.a. the set size) such that the slope of its reaction time graph as a function of the number of distractors is around zero (Treisman and Gelade 1980; Wolfe 1998). This is illustrated in Fig. 1a where the green item pops out from the group of red distractors due to the difference in their color/luminance feature. While the green arrow would continue to pop out regardless of the number of red distractors, a target defined by a unique conjunction of features would not pop out similarly, forcing the observer to scan the displayed visual items one by one until it is found, as shown in Fig. 1b. Naturally, in such a scenario, the time to

**Feature Integration Theory, Fig. 1 Efficient and inefficient visual searches.** (a) When a target is defined by a unique color/luminance feature (the green arrow), it pops out regardless of the number of distractors, a result of a highly efficient search that appears to process all items in parallel. (b) Other searches, in particular, conjunction searches, are much more difficult to resolve, requiring the observer to scan each item separately until it detects the

unique target (in this case, a left pointing green arrow, just as in panel A). (c) Efficient search does not require more time with growing number of distractors, while inefficient search grows linearly. This behavior signals parallel vs. serial processing of the stimulus, expressed clearly by a zero vs. positive slope of the reaction time to target, respectively

find the target will grow (typically linearly) with the number of distracting items, where the performance slope depends on how efficiently the visual system can process the visual features that contribute to the detection. Figure 1b illustrates the expected performance graphs in these two modes.

Following the above, the features of the target and the distractors, as well as their interrelation, determine the visual search mode that is ultimately exhibited in a search task (Nakayama and Silverman 1986). For instance, a considerable amount of evidence indicates that if a target is defined *uniquely* by either color, size, orientation, or motion, it will “pop out” of the display (Wolfe and Horowitz 2004). According to Feature Integration Theory, this is because such features are accessible efficiently to the human visual system during the preattentive stage and their uniqueness signals the location of the target already in the preattentive maps. In other visual search tasks, where targets are defined by less accessible properties or nonunique combinations of properties, the target does not always pop out, forcing the observer to serially search for the target (Wolfe and Horowitz 2004). Hence, which features drive visual attention in visual search scenarios is one of the fundamental questions addressed when conducting visual search experiments. A significant body of research and a variety of theoretical models have been studying this and other aspects of visual search in humans for more than two decades now, and new ways for running countless visual search trials for additional insights have been emerging in recent years. Additional properties of Feature Integration Theory in humans are discussed in recent surveys on this subject (Wolfe and Horowitz 2004).

## Feature Integration Theory Beyond Humans

Indeed, although the research effort mentioned above had followed the ideas of Feature Integration Theory, it has been restricted almost entirely to humans, leaving interesting questions open. Are Feature Integration Theory and its contemporary variations applicable beyond humans? If so,

what features facilitate pop out in different animals? If a preattentive stage occurs in nonhuman animals, do different animals maintain different feature maps? And perhaps first and foremost, since visual search in humans is considered a cortical function, could animals that lack a fully developed cortex be able to perform efficient visual search, and if so, how? These questions are especially interesting given the numerous nonhuman species that depend on vision, and specifically on guided attention, for their survival.

Notwithstanding the extensive research into the visual systems, visual ecology, and visual behavior of nonhuman species, including the type of visual cues that drive their vision, relatively little work has explicitly addressed the features that guide attention, enable pop out, or otherwise affect the efficiency of visual behavioral tasks. Thus, many questions relating to Feature Integration Theory in nonhuman species remain unanswered. And yet, certain studies *have* examined visual search in selected nonhuman species after all. In these studies, the efficiency of visual features is typically determined by the target selection rate (i.e., how often the animal actually finds and selects the designated target), but sometimes also by the reaction time and occasionally by both. Interestingly, many of these studies imply a great deal of similarity in the visual search behavior of humans and nonhumans in both feature search and conjunction search tasks, as this entry discusses below.

But before discussing these details, it is worth mentioning that like many other types of experiments, visual search tasks are far more complicated to perform with animals than with humans. Clearly, it is overwhelmingly simpler to communicate the task to human subjects while animals must be trained to implicitly understand what constitutes the target before it can participate in experiments. Such training can last up to several months (e.g., (Orlowski et al. 2018)) for a single type of experiment, a procedure that much care and patience (by all parties). Furthermore, in the lack of verbal communication, training is required for every new target or visual search experiment. This entails a very time-consuming, multiple-training procedure, if the same animal is to be

tested in multiple types of visual search tasks (as is usually the case in most studies). Another complication in nonhuman visual search tasks relates to the number of consecutive trials a typical subject can participate in. In humans this number is typically determined by cognitive capacity (such as boredom, fatigue, focus, motivation). Animals, on the other hand, are typically rewarded for participation by food portions (unlike payment, course credit, or no reward at all in humans), a mechanism that critically limits the number of trials based on the animal's food intake capacity. Indeed, in reality, an hour's worth of experimentation with human participants might require weeks or months to run on certain animals. Overall, visual search experiments with nonhumans are thus challenging and requires much ingenuity to extract quality behavioral data while preserving the wellbeing of the subjects.

### Feature Integration Theory in Insects

Owing to the methodological difficulties involved, Feature Integration Theory and visual search in general was studied in insects relatively scarcely, where one of the most investigated species in the context of visual search being bees, especially their performance in color feature search tasks. As mentioned above, bees too must be trained for certain behavior in order to allow overt observation of their visual decision, in this case by visit a sucrose solution feeder placed inside an experimental arena near the hive. In a typical experimental trial, the bee enters the arena through a small entrance (Fig. 2a) and then faces a visual search task composed of various visual items (e.g., colored disks) located on the opposite wall. Each such item is equipped with a reward feeder attached to its back and accessible to the bee through a small opening (black dots in Fig. 2a). The bee is required to make a visual decision to obtain the reward while the location of the target and reward feeder change each trial.

The animal's decision, success rates, and response time are documented for the analysis and based on results in such experiments it was

shown that performance in bees varies between species (Morawetz and Spaethe 2012). Specifically, error rates increased as a function of set size but only in honeybees and not in bumblebees (Fig. 2b). At the same time, response time in bumblebees was approximately 30% longer than honeybees (Fig. 2c), although neither species seems affected by set size in a significant way. These findings suggest that the speed-accuracy trade-off to detect the target is species dependent, which the authors attributed to ecological pressure. Given both decision time and error rate, color feature search elicits serial-like search in honeybees and parallel-like search in bumblebees.

### Feature Integration Theory in Birds

Among the earliest nonhuman visual search investigation, even before FIT was conceived, was carried out in the 1970s on pigeons, leveraging the fact that they are relatively easily trained to peck at a selected visual item on a monitor (Blough 1977). Read in the language of the then forthcoming Feature Integration Theory, results indicated that both geometric shape or letters (Blough 1977) were inefficient features that led to longer reaction times and drops in target selection rates as the set size increased. Moreover, pop-out and search asymmetries related to line terminators (Harmening et al. 2011; Orłowski et al. 2015, 2018) were shown to not exist in pigeons (Allan and Blough 1989), unlike in humans. Based on by target selection rates, however, it was shown that pigeons are more efficient at processing color, size, orientation, or shape feature searches conjunction search (Cook et al. 1996).

Using similar pecking response methodology in an operant conditioning chamber, it was later shown that visual search behavior of blue jays incorporates a fundamentally serial component (Bond and Kamil 1999). Trained to detect an image of cryptic moth (namely, the target) embedded in different backgrounds with different levels of crypticity, it was found that reaction time increased and the accuracy decreased as a function of stimulus complexity. However, instead of

**Feature Integration Theory, Fig. 2 Visual search in bees.** (a) A typical experimental arena includes an array of visual items mounted around the access points of reward feeders (Sketch adapted from (Morawetz and Spaethe 2012)). The item in front of the feeder to which bees first approach are considered their visual decision (with some tolerance and decision lines, such as the dotted grid shown, typically employed by the experimenters). (b) Error rate as

a function of set size does not seem to change for bumblebees (dashed and solid black lines) but increases for honeybees (dashed and solid gray lines) (c) The decision time (as a function of set size) of bumblebees (dashed and solid black lines) is approximately 30% longer than for honeybees (dashed and solid gray lines). Values in both graphs are means  $\pm 1$  standard error of the mean (Morawetz and Spaethe 2012)

increasing the number of distracting objects as in a classic visual search experiments, the difficulty level of discriminating between the target and background was increased. In this sense, these results may fit less naturally into FIT. Also, rather than testing how the target's and distractor's features affect visual search per se, the study was aimed to test how the latter is influenced by different procedures (such as cuing and sequential priming) to attain initial focal attention (Bond and Kamil 1999; Goto et al. 2014).

A significant progress using more robust methodology has been achieved in the last decade on what has become a major animal model in nonhuman visual search and saliency

research – the barn owl (Harmening et al. 2011; Orłowski et al. 2015, 2018). Unlike most species, barn owls virtually lack eye movements, which in fact facilitates the overt observation of their visual behavior through gaze tracking from a head-mounted camera, dubbed the OwlCam (Fig. 3a). By using proper image processing and automatic computer vision analyses, it is possible to identify the “functional fovea” and thus the spatial and temporal order of the items that the bird fixates on during free behavior, including flying (Fig. 3b,c), just like the scan path that modern eye trackers would extract from human observers. A series of studies that employed this methodology (Harmening et al.

**Feature Integration Theory, Fig. 3 Visual search in barn owl.** (a) The OwlCam is a tiny wireless video camera that is mounted on the owl's skull and enables a bird's view of its frontal field of view. With proper processing it is possible to generate a panoramic field of view and identify the locations/items that the owl fixates on during search or other visual tasks (Image adapted from (Harmening et al. 2011)). (b) Examples of panoramic scene reconstructions, scan paths (dash lines), and fixations (circles) until the target was first fixated (blue disk) during an orientation task. The numbers near the circles indicate the fixation number. The stimulus arrays contain (from left to right) 16, 36, and 64 items. Note that the number of saccades to the target hardly varies despite the change in set size, indicating that the orientation feature elicits pop-out in

the barn owl (Images adapted from (Orlowski et al. 2015)). (c) A similar panoramic image and scan path during a conjunction search task (in this case, of a target defined by a particular contrast and orientation as illustrated in inset e2). Note the high number (10) of saccades till the target was found, indicating a much more challenging search task for the bird (adapted from Orlowski et al. 2015). (d) Number of saccades and search time as a function of set size clearly shows differences between serial search behavior (solid lines of positive slopes) in a conjunction task (in this case, conjunction of high contrast and orientation) vs. parallel search behavior (dashed lines of virtually zero slope) in feature search task (in this case, high contrast feature search). Data adapted from Orlowski et al. (2018)

2011; Orlowski et al. 2015, 2018) have shown that barn owls exhibit both parallel and serial search modes in a fashion extremely similar to humans. Stimuli in these experiments were either projected or physically organized as real objects on the floor in front of animal subjects, and the dependent variables employed were the number of saccades and search time until the target was found. Both indicators, when examined as a function of set size, have indicated that orientation and luminance-contrast search tasks elicit pop-out and parallel search mode (Harmening et al. 2011; Orlowski et al. 2015) while low-contrast feature tasks and certain conjunction tasks elicit serial search (Orlowski et al. 2018) (Fig. 3d).

## Feature Integration Theory in Fish

In the aquatic world, one of the most extensively studied species for its visual search behavior is the archerfish. This fish is especially well-known for its incredible hunting skill of *terrestrial* insects that rest on foliage and low-lying branches by shooting them with a strong accurate jet of water from his mouth. This extremely fantastic behavior is often attributed (in part) to excellent eyesight and unique neural computations (Ben-Tov et al. 2018; Vasserman et al. 2010), and since it is possible to train the archerfish to shoot at artificial objects presented on a monitor, it allows controlled behavioral experiments where the fish's visual decisions can be easily observed.

Using this animal model, it was first shown that the archerfish exhibits both parallel and serial search modes (Ben-Tov et al. 2015, 2018; Mokeichev et al. 2010; Rischawy and Schuster 2013). Since initial work sought to leverage the high responsiveness of the archerfish to movement, stimuli typically incorporated moving bars. However, more recent work showed that the archerfish not only exhibits pop-out behavior, but that the latter is facilitated by four common visual features known to elicit the same behavior in humans, namely color, size, orientation, and motion (Reichenthal et al. 2019). That was also an early demonstration that shape tasks elicit serial search, with reaction time that grows, and target selection rate that decreases, with the number of distractors. Additionally, it was also shown that conjunction search tasks of size and color are asymmetric. Parallel search was elicited in the archerfish when a large blue target was embedded in a field of small blue and large black distractors, but serial search was elicited for a small blue target amidst small black and large blue distractors.

A very recent follow-up (Reichenthal et al. 2020) has further extended these findings and explored the possibility that fish performance exhibits the same continuum found in human vision (Wolfe 1998). Unfortunately, at the time of this publication, the relatively small total number of trials in the literature that have tested archerfish in visual search still prohibits comparable conclusions, but given these scant data, and inspired by Feature Integration Theory, Reichenthal et al. (2020) have been able to categorized archerfish performance based on the classical bimodal (easy/efficient/parallel vs. difficult/inefficient/serial) Feature Integration Theory division (Treisman and Gelade 1980) in a rigorous fashion, concluding that ~45 ms/item is a proper threshold between the two behaviors (as depicted by the black dashed line in Fig. 4b), compared to 5 ms/item attributed to humans. Apart from this expected species-dependent response time threshold, performance of humans and archerfish was found qualitatively similar, and in particular all features of color, size, orientation, and motion elicited the same type of visual search behavior in both (Reichenthal et al. 2020). Similar

behavioral similarity between the species also was observed in conjunction search tasks (in that case of size and color), both in the type of performance (i.e., parallel vs. serial) and in terms of performance asymmetries (i.e., when switching the role of targets and distractors. Note that as discussed above, these findings also match those in birds, where behavior was found qualitatively similar to humans, differing quantitatively only in the scale of response time (Harmening et al. 2011; Orłowski et al. 2015, 2018).

That being said, the same experimental methodology used to study the archerfish revealed qualitatively different behaviors compared to humans when the search is governed by target shape. For example, while searching for a solid disk amidst Pacman like distractors is easy (parallel) for humans, it was found difficult (serial) for archerfish. Yet, when the targets were Q-like shapes amidst full disk distractors, performance was qualitatively similar again, that is, parallel in this case. This inconsistent comparison in different cases could arise from the difference in familiarity of the species to certain shapes and/or to negative shape associations (e.g., due to fear, see e.g., Öhman et al. (2001), that certain shapes could generate in each species.

Overall, taken as a primary animal model, the archerfish indicates that Feature Integration Theory is indeed applicable to fish and humans alike, except when it depends on shape processing that may be species-dependent. While the archerfish provides an excellent platform for such research, exploring visual search (or any other visual) behavior in other (more “traditional”) species of fish clearly requires other means of probing their visual decisions, for example by training them to approach the target. Using such methods, it was indeed demonstrated that zebrafish exhibits pop-out in color feature visual search (Proulx et al. 2014).

## Feature Integration Theory in Nonhuman Mammals

Given findings as described above, one would expect visual search in mammals to lead the

**Feature Integration Theory, Fig. 4 Visual search in fish.** (a) Archerfish can be trained to perform visual search tasks on a monitor, very much like human subjects. Their visual decisions are observed overtly (and recorded with a video camera) based on the target that the fish shoot at. (b) A summary of archerfish vs. human performance in various visual search tasks that were performed *identically* on the two species. The sole difference in the analysis is based

on the scale of response times that cannot be identical for both species. However, the threshold between parallel and serial modes can be determined by the same method for both species (as described in Reichenthal et al. 2020) and is marked by the dashed horizontal lines. Search mode that was elicited by both species is identical in virtually all search tasks, except for one specific case that involves shape processing (disk vs. Pacmen)

way. It is thus surprising that nonhuman terrestrial mammals have not been widely studied in the context of visual search, with primates, and especially monkeys, being by far the most studied animal in this group. The methodologies employed in these studies vary significantly.

In the classic visual search experiment by Bichot and Schall (1999), both saccade latency slope and error rates were measured in macaque subjects as a function of the set size, to demonstrate that color and simple shape searches are more efficient than their conjunction counterparts (Fig. 5a). Such insights were further supported by a forced-choice target detection paradigm that indicated that time-to-detection for targets defined by color does not depend on

set size (hence, they pop out), whereas targets defined by shape, or a conjunction of shape and color, lead to reaction times that increase with set size (Buračas and Albright 1999; Wardak et al. 2012) (Fig. 5b). Unlike Bichot and Schall (1999), the latter used a more direct procedure where the task of the monkey was to press a lever only when the stimulus contains a target, and to abstain from response in target-absence trials. While more difficult to analyze from Feature Integration Theory's perspective, other visual search experiments also demonstrated influence of emotional aspects, like threat, of the efficiency of visual search (Shibasaki and Kawai 2009) as well as the capacity of monkeys to perform serial visual search based on more complicated

**Feature Integration Theory, Fig. 5 Visual search in mammals.** (a) Saccade latency as a function of set size in macaques (Bichot and Schall 1999) suggests that feature search tasks elicit pop-out while conjunction searches lead to serial search. (b) Searching for the pink diamond in these tasks led monkeys exhibit pop-out (parallel search mode) in color feature searches, but serial mode in complex shape or conjunction searches (graph colors code the same

experiments as the panels on the left; adapted from (Wardak et al. 2012). (c) Visual search response time in rats did not change with set size in a feature task (dark gray) or a conjunction task (light gray). Accuracy, on the other hand, did decrease as a function of set size (Botly and De Rosa 2012), leaving the evidence so far ambiguous regarding the search mode or even the search goal employed

combination of feature. Furthermore, monkeys also demonstrate the classic speed-accuracy tradeoff found also in human visual search (Tomonaga and Imura 2015).

Unfortunately, very little visual search exploration has been performed thus far on nonprimate mammals, perhaps a result of methodological complexities. A notable exception involving rats has demonstrated that unlike monkeys this species exhibits a somewhat mixed performance, with essentially fixed reaction times but error rates that increase with set size, all for targets defined

by luminance, shape, and certain conjunctions (Botly and De Rosa 2012) (Fig. 5c).

## Epilogue: Is Animal Advantage Possible?

To date, the literature on Feature Integration Theory in animals that has been summarized above supports (at least implicitly) the idea that visual search behavior is similar in humans and in many animals, and in particular that whatever pops out to animals also pops out for humans. The

converse, however, is not always true and a few experiments have indicated that while certain shape tasks pop out to humans, they do *not* do so for animals. This “one way” advantage in performance may be explained by the fact that the human visual system is much more developed and facilitates complex processing much faster and better than animals, whereas many basic pop-out features are universal in nature and thus affected many species in the course of evolution. This intuition thus raises a simple but interesting question of whether there are any visual tasks on which animals outperform humans. Clearly, Feature Integration Theory neither excludes nor necessitates this possibility, and to date this question remains largely open.

And yet, some speculations can be made. Obviously, visual properties that humans cannot observe at all will naturally give animals (that can sense them) an edge when such properties define the target. For example, if the target is composed solely of the polarization of the light it reflects or by wavelengths outside the visible spectrum, it may pop out to certain animals but not for humans. Naturally, our open question does not refer to such cases. But in the spirit of ecological vision, and hard evidence about the effect of the natural environment on neural processing, a habitat abundant with a certain visual cue, feature, or property that are rare in human life could pop out to certain animals living in that environment but not to humans. For example, it is tempting to hypothesize that certain visual search experiments based on unique shapes would elicit effective (parallel) search in a particular animal but serial search in humans. This type of experiment would need to revolve around a typical shape from the animal’s habitat, which rarely exists or completely absent in human environments. For example, human face targets, but not animal faces, pop out to human observers when presented amidst non-face objects, and this is despite the many similarities one can draw between animal and human faces (Hershler and Hochstein 2005). If such effect also generalizes to other species, one may that a fish figure or fish face would pop out for fish and not for humans. Recent preliminary

investigations in this direction have yet to generate a suitable demonstration of such animal advantage and dedicated research is needed to resolve this open question.

## Fecundity

Kostas Ganias

Aristotle University of Thessaloniki,  
Thessaloniki, Greece

## Synonyms

Fertility; Reproductive output; Reproductive potential

## Definition

The number of gametes produced by an organism

## Introduction

For all animals, fecundity is a measure of gamete production expressing the number of eggs or sperm produced by females and males, respectively. In that respect, fecundity is a quantitative variable differing from “fertility” and “reproductive potential” which are more general and qualitative terms expressing an individual’s reproductive success and its capacity to produce gametes and viable embryos, respectively. Fecundity measurements are of particular importance in animal biology and ecology since they are used for assessing population reproductive dynamics and energetics and for estimating their annual reproductive output and how it is linked to recruitment and population growth (Stearns 1992). In addition, measurements of fecundity can be

implemented in the appraisal of biomass of ecologically or socially important species, especially in commercial fishes. There are several measures of fecundity such as the daily or the (potential) annual fecundity, the absolute or the relative fecundity, the determinate or the indeterminate fecundity, etc. (Hunter et al. 1992). Given that individual cells of young embryos all originate from the zygote – the fertilized egg – most focus in fecundity assessments in population biology and ecology has been given to reproductively active females.

## Fecundity Measurements

Fecundity measurements vary based on the modes of reproduction animals use to produce their young. In viviparous organisms, like placental mammals, fecundity is usually measured as the number of litters per year while in humans approaches to measuring fecundity include the

assessment of time to pregnancy and day-specific probabilities of conception (daily fecundities) indexed to a day of ovulation. On the other hand, in oviparous animals, fecundity measurements are typically performed through direct counting of eggs in oviposition sites such as nests. In broadcast spawners – most aquatic animals, except for aquatic mammals and reptiles – which release their gametes into the water, fecundity measurements should rather be based on oocyte counts in spawning capable females. In highly fecund spawners, like most teleosts, fecundity measurements are carried out in smaller fractions of ovarian tissue of known weight/volume and resulting oocyte densities are extrapolated to the total weight/volume of the ovary (gravimetric or volumetric method respectively).

Apart from their number, the size of oocytes can also be important in fecundity assessments. The resulting oocyte size distributions (Fig. 1) provide an illustration of the fecundity production process which is particularly helpful for

**Fecundity, Fig. 1** Oocyte size frequency distributions from a marine teleost fish (sardine, *Sardina pilchardus*) arranged in ascending order of mean oocyte size. The plot illustrates the gradual growth and separation of the spawning batch (arrow) from the smaller oocytes of the ovary in sequential stages of development. *VIT-1 to 3*: various stages of true vitellogenesis; *GVM* germinal vesicle migration stage, *HYD* hydration stage (typical in marine teleosts).

disentangling total fecundity from batch size in fish. Traditionally, these measurements are performed by averaging the maximum and minimum axes in a number of oocytes through direct observations under dissecting microscopes. However, these traditional methods not only are painstaking and labor-intensive but can also be inaccurate due to biased selection of oocytes, repeated measurements, etc. Undoubtedly, one major improvement in fecundity assessments was the automation of the process of measuring and counting oocytes through image analysis systems which is a friendlier and more cost-effective means to estimate fecundity (Fig. 2). Another important advance deals with the quantification of various follicular types such as previtellogenic oocytes, atretic and postovulatory follicles that may only be identified through ovarian histology through stereological methods.

## Fecundity Production and Temporal Dynamics

For a reproductive event to occur, oocytes must be recruited to the appropriate developmental stages at the right time so that species can breed when there is potential for reproductive success. There are three key fecundity recruitment events (Wallace and Selman 1981): (1) from oogonial nests to primary growth oocytes; (2) from primary to secondary growth oocytes; and (3) into oocyte maturation. Recruitment to primary growth is responsible for populating the ovary with primary growth oocytes which are seldom taken into account although clearly play a role in the process of sexual maturation. Recruitment to oocyte maturation is indicative of an individual's commitment to imminent egg laying. However, it is the frequency and patterns of recruitment to

F

**Fecundity, Fig. 2** Measurement of oocyte size and number in a small sample of a fish ovary (whole mount) by means of particle analysis.

secondary growth which are commonly used in assessments of fecundity production.

Fecundity temporal dynamics commonly occur at four temporal scales (Lowerre-Barbieri et al. 2011; Ganas and Lowerre-Barbieri [accepted](#)): lifetime, annual, intra-seasonal, or diel. At the lifetime temporal scale, the number of breeding opportunities (i.e., semelparous vs. iteroparous) is dependent on whether recruitment from primary to secondary oocyte growth is “complete” or “partial.” At the annual scale, fecundity production is performed in two distinct breeding patterns: single and multiple breeding. Single breeders lay all their eggs in one event or over a very short time period within the reproductive cycle while multiple breeders develop and release more than one batch of eggs within a spawning season. Fecundity type (determinate or indeterminate) is determined at the intra-seasonal scale by whether oocytes to be spawned in a given breeding period continue to be recruited to secondary growth within the breeding period or not. Species with determinate fecundity exhibit “restricted” recruitment, recruiting all oocytes which will complete vitellogenesis and be released in a reproductive cycle prior to the beginning of the breeding season. Recruitment to oocyte maturation is usually performed at the diel scale and as said above is indicative of imminent breeding event.

## Fecundity Dependencies and Trade-Offs

Life history theory predicts that fecundity in animals is interdependent with maternal size, offspring size, and egg mass. Such dependencies and trade-offs are reflected in patterns of parental care, recruitment, population growth, and mortality that profoundly affect the ecology of the species. However, it is the trade-off between fecundity and individual size of the offspring that mostly dominates the allometry of those variables and the analysis of gross patterns among different animal groups shows two distinct modes with strong taxonomic effect (Visman et al. 1996): low fecundity and large offspring size which is a general characteristic of amniotes (mammals, reptiles, and birds), and high fecundity

and small offspring size which is mostly prominent in anamniotes (fish and amphibians) and other lower taxonomic groups such as crustaceans. For example, fecundity in fish increases with age and size of the female both within species (Blaxter 1969) and among species (Duarte and Alcaraz 1989), while among amniotic organisms fecundity is only loosely, and negatively, related to female mass (Visman et al. 1996). It is interesting to point out that viviparous or ovoviviparous anamniotic organisms such as most elasmobranchs (e.g., chimaeras, sharks, and rays) deploy the low fecundity and large offspring strategy (Goodwin et al. 2002), clearly suggesting that the evolution of strategies mostly deals with parental investment and survival rates of individual offspring (Winemiller 1989). For example, again amongst fish, fecundity tends to be higher in marine fish than in freshwater fish (Duarte and Alcaraz 1989), while multivariate methods across a wide range of species identified that high fecundity is generally grouped together with delayed maturation, fewer reproductive events, shorter breeding season, and vice versa (Winemiller 1989). Physiological constraints, e.g., the trade-off between oocyte number and size within the finite abdominal cavity, geographical trends such as latitudinal clines, and genetic variation may also affect animal fecundity (Stearns 1992).

## Definition

The feed industry refers to the production of feeds and feedstuff for consumption by animals,

whether production, companion, or managed wild and exotic species. The feed industry is also responsible for the production of feedstuff for use in aquaculture.

## Introduction

The **feed industry** is a global, multibillion-dollar industry that is critical for both human and animal nutrition. The feed industry is typically viewed as distinct from the food industry which produces food and foodstuff for human consumption, although both industries are clearly linked, with the feed industry supporting the production of animal products destined for the human food chain. In livestock production systems, feed constitutes the major expense associated with output, typically exceeding 50% of total costs involved. For this reason, the feed industry must consider the economic viability of feed production, from individual raw materials to diet and ration formulation. Equally, the feed industry typically also benefits from the utilization of co-products and by-products from the human food industry that are not otherwise used or consumed due to reasons of choice or culture.

Consequently, as it is responsible for providing safe, nutritious, sustainable, suitable, cost-effective, and accessible feedstuffs for animal consumption either directly or indirectly, the feed industry is one of the most responsive and important global industries. However, the feed industry is increasingly facing challenges in many forms, and issues of sustainability are driving rapid and specific changes. As a result, the feed industry heavily relies on scientific and technological advances to ensure currency, economic security, and environmental sustainability.

The feed industry researches, develops, formulates, and produces feedstuffs suitable for a range of species, from production, companion, zoo, and even managed wild species when supplemental feeding might be initiated. Developing feedstuffs for production animals is, however, a key component of the feed industry. Food (and ancillary) products derived from cattle, sheep, pigs, poultry, and aquaculture continue to comprise a large

proportion of the Western diet (Sapkota et al. 2007), highlighting the link between the feed industry and human food production. Furthermore, as the global human population continues to expand and the demand for animal-derived protein increases as a result, the feed industry is tasked with finding ways to maximize production in a safe, sustainable, affordable, and ethical way.

## The History and Development of the Feed Industry

All organisms need food for survival. Food supplies key nutrients to support growth, activity output, recovery/regeneration, and production. For organisms that do not acquire their own food through free grazing or predation, the feed industry is essential for ensuring that suitable feedstuffs are available and accessible. The feeding of production animal species particularly has seen dramatic changes in the last century and continues to meet new challenges in the sustainable provision of feeds and feedstuffs. Animal nutrition as a scientific discipline first began to develop in the early 1800s (Coffey et al. 2015), and the modern-day feed industry is now responsible for the production of nutritious and safe feedstuffs to feed production animals such as cattle, sheep, pigs, poultry, and farmed fish and for use in other aquaculture systems.

The feed industry is also involved in the research, manufacture, and provision of feedstuffs for other species such as companion animals that, while not necessarily destined for human consumption, still require safe, nutritious, and effective feeds. Notably, there has been an increase in the humanization of pet diets (Clemens 2014), concurrent with increased owner awareness of their own health and diet. This leads to additional challenges for the feed industry, to meet owner-driven demand for dog and cat diets, to be rich in animal-derived protein (Okin 2017).

The development of the feed industry on a large scale has been gradual, and early beginnings in the production of animal feeds and feedstuffs, in concert with specific animal management practices, likely date to approximately 12,000 years

ago (Coffey et al. 2015). As the human population gradually moved from a nomadic, hunter-gather existence to an agrarian, settled existence, the reliance on hunting as a source of nourishment decreased, and instead, crops were grown, and animal species domesticated as food sources. At this point, the agricultural production of food became important, for nourishing the animals used as a source of milk, meat, wool, and hides and thus to support human nutrition and survival. The evolution of modern agricultural practices and the increased intensification of animal production have necessitated the development of an industry that can support both nutritional and production requirements of fed species. Indeed, the development of the feed industry is closely linked with the development of intensified agricultural production, notably the movement of animal production from open, expansive grazing to confinement and intensive housing practices (Coffey et al. 2015). This has coincided with the global expansion and technological development of the human population, in addition to a move toward a more urbanized existence.

Historically, feed production would have been on a small scale, with individual farmers growing and producing enough food for themselves, their animals, and perhaps their small, local community. As populations expanded, however, such subsistence production became less viable, and economies of scale started to have an impact. Farms have steadily increased in size and rates of production output have increased substantially. The increased urbanization of the human population has further reduced the proportion of the human population employed or involved directly in food production, necessitating more intensive feed and food production practices to be adopted (Satterthwaite et al. 2010). As a result, the feed industry is under substantial pressure to meet increasing demands of a growing human population and an increased reliance upon and desire to consume animal-derived products. This is combined with commercial pressure to feed the global human and animal population safely and sustainably, from both economic and environmental perspectives. Indeed, by 2050, it is estimated that the human population will exceed nine billion and

that the required food will be 60% higher than that at present (IFIF 2019), highlighting the need for an efficient and effective feed industry. Food safety continues to be a significant consideration, with the quality of animal-derived end products being related to how those animals were originally fed and managed (e.g., see (Zaghini et al. 2005)), so the feed industry must strive to balance demands from a production and consumer perspective.

Indeed, the feed industry is significantly affected by issues and concerns relating to human consumers. The consumption of animal-derived products is directly affected by the wealth of the human population (McDonald et al. 2011), with wealthier populations typically demonstrating increased consumption and utilization of animal products. Indeed, global inequalities, natural disasters, conflict, and other crises continue to affect the provision of human-destined foodstuff, and it is estimated that 800 million people remain chronically hungry, with approximately 2 billion suffering from various micronutrient deficiencies (FAO 2017). Culture and religion also play a part in determining specific animal production, and increasingly, consumers are making consumption choices based on ethical, moral, or health concerns (McAfee et al. 2010). This is also observed in the choices that human caregivers are making in companion animal diets, with increased humanization and perceived quality choices leading to diets for cats and dogs being formulated to meet human demands rather than animal nutritional requirements (Clemens 2014). These factors all impact on the feed industry and further challenge it to respond to environmental, health, welfare, safety, and integrity concerns.

## The Scientific and Technological Development of the Feed Industry

The feed industry has benefitted significantly from scientific advances in the understanding of animal nutritional requirements and how nutrition can impact upon performance output. Nutrition is widely viewed as a controllable variable that can support an animal reaching its genetic potential

for a given production output and has seen significant scientific advances since the early 1800s (Coffey et al. 2015). Genetic advances in livestock have also meant that there is increased homogenization of breeds/types and the required nutrient provision for consistent production output. The first commercial, compound feeds were developed for feeding horses and mules in the 1800s. These animals were critical for providing transport and draft power and, as such, required consistent and quality feedstuff (Coffey et al. 2015). As the production of livestock continued to expand and develop, with improvements in feed conversion rates and efficiencies in different species, the feed industry has further developed via consolidation, automation, scientific research, and technological innovations, to support altered rates of growth, nutrient requirements, and specific production targets of livestock species. The modern feed industry is now highly automated and specialized and functions on large economies of scale.

As livestock species have developed, the feed industry has had to respond. The broiler chicken demonstrates an extreme example of intense selection for production traits since the 1950s, with the modern-day broiler now reaching slaughter weight in significantly fewer days and thus with less feed intake than historic forms (Tallentire et al. 2016). Indeed, the broiler chicken has demonstrated an increased growth rate of over 400% between 1950 and 2005 (Zuidhof et al. 2014), revealing the extent of livestock genetic improvements. As a result, nutrient provision for livestock by the feed industry is under constant review, with research and innovation driving advances.

Technology within the feed industry is also critical for developing effective manufacturing and feed provision strategies, to reduce spillage, wastage, and contamination. Improvements in how animals are fed directly reduce waste and improve overall efficiency (Svihus et al. 2004). It has also been observed that more commercial, heavily selected breeds of broilers have reduced levels of feed wastage and spillage (Zuidhof et al. 2014), in addition to increased growth rates and voluntary food intakes (Schmidt et al. 2009).

Maximal utilization of feed is just one way of managing and meeting sustainability targets by the feed industry.

## Feed Ingredients, Safety, and Production

The feed industry relies on raw ingredients that are both animal and plant in origin. The target animal to be fed and its nutrient requirements, as well as its digestive strategy, will determine what ingredients will be utilized. Typically, national and international organizations also regulate what ingredients are acceptable within animal diets and at what levels, identifying those that are legally permitted for animal consumption. This is necessary to ensure safety and suitability.

For many production species, diets are formulated to be compound feeds, consisting of several raw ingredients, combined to create a complete and balanced diet. Cereals, grains, and other plant-derived materials (including by-products from human food production, such as fruit pomaces) will provide ready sources of protein, fats, fiber, and other nutrients. Care must be taken to ensure the quality of many plant ingredients, notably cereals that can be contaminated with mycotoxins, potentially hazardous to both animal and human health (Hussein and Brasel 2001). Maximum levels of key mycotoxins in finished feed products are identified, but monitoring is critical, especially due to geographical and seasonal variation in their occurrence.

Ingredients derived from animal products and by-products (such as rendered meat meals, feather meals, and blood meals) can also be incorporated into feeds for certain species, again providing rich sources of key nutrients, especially protein. Similarly, in some countries, animal waste products are incorporated into animal feeds as a protein-rich, sustainable raw material, although this is not endorsed by the US Food and Drug Administration (FDA), with concerns about pathogen and drug residue transfer (Sapkota et al. 2007).

Indeed, the inclusion of animal-derived products within animal feedstuffs, especially for target

species that are not omnivorous or carnivorous, is an area of interest, with concerns relating to pathogens, heavy metals, and dioxins being present. A significant example of this is the prion-mediated disease, variant Creutzfeldt-Jakob disease (vCJD) in humans (Collinge 1999), that was transmitted to humans via the consumption of prion-infected meat and linked to historic practices of feeding cattle rendered animal protein, containing prions from cattle infected with bovine spongiform encephalopathy (BSE).

Other pathogenic agents can be transmitted via feeds and foodstuffs, such as *Salmonella* spp. (Crump et al. 2002), *E. coli* (Dargatz et al. 2005), and antibiotic-resistant bacteria, this having become especially problematic and of concern in some raw meat-based companion animal diets (Nüesch-Inderbilen et al. 2019). Dry pet foods have also been associated with *Salmonella* infection risk (Barton Behravesh et al. 2010), highlighting the importance of high production and safety standards within the feed industry to minimize contamination of finished products.

Contamination of animal feed with such pathogens can occur at many stages of production, but their potential impact on both human and animal health highlights the importance of balancing efficiency and sustainability with safety and ensuring active collaboration between relevant regulatory bodies and food/animal health professionals (Sapkota et al. 2007).

## New and Alternative Ingredients in the Feed Industry

The pressure for the feed industry to remain both economically and environmentally sustainable means that the industry is increasingly researching and examining the use of alternative, novel, and by-product ingredients within the manufacture of feedstuffs. Since the 1970s, the feed industry has benefitted from several advances in feed production, both nutritional and technological (Coffey et al. 2015). The intention is threefold: to minimize and reduce waste, to enhance nutrition, and to ensure economic and feed efficiency where possible. This is where previous lessons

learned from including ingredients into animal diets are critical (such as the prion diseases vCJD and BSE). However, novel algal, plant, and insect ingredients are being explored for use in feedstuffs (Coffey et al. 2015; van der Spiegel et al. 2013), although queries regarding aspects of safety, legislation, and nutritional value for some novel ingredients remain and further research is needed. However, in the pursuit of economic and dietary efficiency, it is likely that novel additives and ingredients will form an increasingly large portion of the animal feed industry in the future.

## Feed Analysis and Standards

In order to produce nutritionally appropriate and adequate feedstuffs, the feed industry is dependent upon the ability to analyze both raw ingredients and finished feed products. Early systems of feed analysis and standards related to the development of comparative measures, allowing different feeds to be compared. The “proximate analysis system” which remains in use for basic analytical comparisons of feedstuff even today (crude protein, crude fiber, crude fat, ash, and moisture) was developed in Germany in the mid-1800s and permitted nutritional values to be ascribed to feeds, based on chemical analysis. Awareness of digestibility of nutrients gradually developed, and the energy content (from fats, proteins, and carbohydrates) of a given diet could be determined via analytical techniques. The determination and definition of calorie equivalence of fat, protein, and carbohydrate was pioneered by the US scientist, W.O. Atwater (Nichols 1994). Atwater is also credited with the general introduction of the term and definition of the calorie in an 1887 article (Hargrove 2006). Indeed, Atwater was pivotal in the analytical determination of the physical energy of feed and proximate analysis, and his work continues to underpin proximate analytical techniques in the modern feed industry.

The development of feed standards and associated analytical techniques was further supported by accumulating evidence regarding the specific nutrient requirements of individual species, including vitamin and mineral requirements.

This information was primarily generated in the mid-twentieth century, concurrent with increased intensification of agricultural animal production systems and commercialization of the feed industry. One key development was the publication of nutrient requirement tables for individual species by the Committee on Animal Nutrition of the National Research Council in the USA, in 1944. The NRC nutrient requirements for species as diverse as cattle, poultry, horses, dogs, and cats are regularly updated and continue to remain as key global animal nutrition resources and standards for diet formulation and animal nutrition research.

The feed industry has also had to remain responsive to advances in the genetic management of the raw materials produced and target species fed. Heavy genetic selection for both crop and animal species that demonstrate enhanced levels of productivity, environmental resilience, improved health and disease resistance, and in the case of many animal species from cattle to poultry, significantly improved levels of feed conversion efficiencies has resulted in the feed industry having to adapt.

Genetic improvements and enhancements of crops and other raw materials incorporated into diets can also impact on the mineral density and other nutrient characteristics. Diet formulation consequently needs to be dynamic and capable of assessing this impact and managing overall utilization of such raw materials. The application of fertilizers and other substances to crops can also impact on their value as raw ingredients, with the potential of increasing levels of substances (such as nitrates), that can be toxic to fed species at certain levels. Consequently, monitoring is critical to ensure safety at all levels of the feed chain.

## Diet Formulation

The feed industry is dependent upon the application of nutritional science in both the formulation of effective diets for target species and the safe, effective, and efficient production of such diets. Depending on the target species and ingredient availability, formulated diets will vary in

composition. For many production species, compound feeds are prepared from several ingredients, including vitamins, minerals, and other nutritional and technological additives such as antioxidants and preservatives. For other species, notably those predominantly consuming browse, fodder, or forage material, the material itself will be analyzed and that information used to develop supporting diets to ensure nutritional adequacy.

Diet formulation is typically achieved *in silico*, whereby fundamental nutritional knowledge regarding the nutritional requirements of the target species for specific production levels is met by selecting dietary ingredients at the correct levels (often on a “least cost” basis) to meet daily nutrient needs. Formulations can be developed either as “fixed” or “variable” formulas, with fixed formulas being consistent in the ingredient composition and amount, and variable formulas differing in fundamental composition, but consistent in analytical nutritional content. Economic pressures often mean that variable formulas are more viable as they permit alternations of ingredients on a cost basis while still meeting the required nutritional analytics.

Conversely, fixed formulas are often viewed as more desirable, although they can be problematic from the perspective of raw material variation between batches and can be affected by price fluctuations in raw materials. This lack of flexibility can also negatively impact upon the nutritional content and performance of the finished product. However, notably in the pet food industry, fixed formulation diets are typically regarded as preferable and attract a premium, in contrast to variable formulation diets. This is largely a consequence of the humanization of the pet food market and a perception of quality and consistency that is not necessarily based on sound nutritional science.

## Pressures on the Feed Industry

The global feed industry increasingly must meet several challenges. The sustainability of food production and allied agricultural systems is under intense scrutiny because of increasing pressures

on limited global natural resources. Land, water, and other natural resources are under threat, despite technological and productivity enhancements. Deforestation, depletion of soil integrity, and the climate change crisis are creating a situation where increased yield is expected and required, from both crops and animals, but is hampered by natural and anthropogenic factors limiting output potential. This is combined with the prediction that the world’s population is anticipated to reach 10 billion by 2050 (FAO 2017) and the pressure on the feed industry to support the human demand for animal products, especially, is clear.

Consequently, the feed industry is facing a future with substantially increased demands on production output while balancing the utilization of land and other natural resources in a safe and sustainable way. Organizations such as the International Feed Industry Federation (IFIF) respond to these demands by recognizing the need to manage the industry in an effective way. For example, the IFIF identifies three pillars as underpinning the strategic objectives of the industry: sustainability, regulatory and industry standards, and education and the sharing of best practice (IFIF 2019). Recognizing the global responsibilities of the industry is critical to its continued success and ability to meet demand while ensuring safety, integrity, and sustainability.

Sustainability is a key responsibility of the feed industry, and with the wider human population increasing taking a more critical stance over the global impact that animal and feed production has, there is a real need to demonstrate progress and improvements. Notably, the genetic advancement of both crop ingredients and fed livestock is a significant part of this. Where crops have been selected for improved yield, desiccation tolerance, and resistance to pests and diseases, this leads directly to efficiency savings and reduced environmental impact. Similarly, species, such as the broiler chicken, that demonstrate improved feed conversion efficiencies and time to slaughter, will need less nutrition and food intake over their lifespan, excrete less, and have less indirect environmental impact through fossil fuel use (Pelletier 2008). These factors are integral to the ongoing

development of sustainability actions within the feed industry.

From a global perspective, the feed industry must also remain responsive to demands and regulations from individual and collective governments, relating to aspects of feed safety, feed quality, and feed integrity. The safety of feedstuffs relates to the potential health hazard that ingredients or compound feeds could pose to fed animals, or indeed the subsequent products intended for human (or other animal) consumption (Hoorfar et al. 2011). Feed quality reflects the nutritional value of ingredients and feedstuff to support the physiological and health and welfare demands of fed animals. Consequently, feed quality will have a direct impact on the quality of end products also. Finally, feed integrity is essential to ensure the traceability and provenance of feed materials, an aspect of increasing importance given the consumer desire for specific characteristics such as organic origin as opposed to conventional feed and food production (Hoorfar et al. 2011).

## Conclusion

The global feed industry is a rapidly evolving industry and is under increasing pressure to respond and adapt to the requirements of high feed conversion efficiency, sustainability, affordability, and technological and scientific advances in terms of animal nutrition. Consumer demand for safe, nourishing, and appropriate foodstuff for their direct consumption and for feeding production, companion, and wild species similarly drives industry developments to ensure efficiency, integrity, safety, and sustainability.

Production animal nutrition has been the cornerstone of the development of the feed industry and remains a significant driver of technological advances. As the global human population continues to increase and the corresponding requirement for animal-derived products increases, the feed industry needs to continue to identify ways to enhance productivity and feed conversion efficiencies while remaining sustainable and cost-effective. Ensuring animal health and welfare is also an important aspect of the feed industry,

and progress continues to be made about understanding specific nutritional requirements of individual species, as well as advances in nutritional science. It is likely that the feed industry will continue to adopt enhanced technologies and utilize novel ingredients and additives in the drive to meet sustainability, welfare, and feed conversion efficiency goals in the future.

Feeding companion animal species involves additional challenges, notably the increased humanization of “pet” species. Consumers choosing foods for their companion animals are increasingly aware of ingredients, processing, transparency, traceability, and potential safety issues. The feed industry has a responsibility to meet these demands with a strong evidence base. Consequently, the sector of the feed industry concerned with companion animal nutrition must acknowledge the human-animal bond and how this affects consumer behavior and purchasing choices. Balancing robust scientific knowledge in the formulation and development of foodstuffs, alongside meeting the marketing requirements for a competitive and highly commercial industry, is a significant challenge for the feed industry moving forward while still factoring in affordability and sustainability.

**Definition**

Feline Cognition: A wide range of feline experiences that inform behavior including sensing, perceiving, learning, remembering, and reasoning.

**Introduction**

Felines are a diverse group of carnivores that belong to one of two classifications – either the big cats, *Pantherinae*, or small cats, *Felinae*, to which the domestic cat belongs. Felines inhabit a range of environments from jungles and savannahs to human homes. The domestic cat has been particularly successful in its social relationship with humans and has lived in association with humans for thousands of years, with the first domestication of cats hypothesized to have begun around 9000 years ago (Ottoni et al. 2017). Despite human’s long-standing association with both wild and domesticated cats, relatively little is known about feline cognition, especially the cognition of non-domestic feline species. However, the research that does exist provides evidence of a family of mammals that has evolved to successfully perceive and navigate their surroundings, learn about their environment, and display an array of social relationships with both asocial and social species represented.

**Perception**

Perception is the process by which an individual becomes aware of stimuli in the environment

through their senses. Domestic cats (*Felis silvestris catus*) have served as a model species for perception research over the last century, informing much of what we know about both the cat and human perception systems.

Domestic cats have several senses equipped to bring in information about the surrounding environment. Tactile and olfactory systems are functional at birth indicating these senses are vital in the early days of a kitten's life. As kittens age, their auditory system develops and kittens begin to orient to auditory stimuli at 11 days old and follow auditory stimuli at 15 days old. Slightly later, kittens begin to orient to visual stimuli, around 16 days old, and follow visual stimuli at 18 days old with the ability to complete more complex visual tasks occurring after 25 days of age (Norton 1974).

One such visual task includes the use of a visual cliff test, which assesses the animal's ability to use visual cues in their environment to perceive depth. For example, domestic kittens are placed on a raised apparatus of which half is covered in a checkerboard pattern (shallow side) and the other half is covered in Plexiglas, with a checkerboard pattern underneath at ground level (deep side). If kittens are able to determine depth, they should not cross over into the Plexiglas area, as this would be perceived as a drop-off. Indeed, kittens displayed the ability to discriminate depth at around 27 days (Walk and Gibson 1961).

Does domestication influence the perception of stimuli on these visual tasks? Another study examined the behavior of kittens of several species including tigers (*Panthera tigris*), jaguars (*Panthera onca*), and snow leopards (*Panthera uncia*) on the visual cliff test. Researchers found that just like domestic kittens, non-domesticated felines also display depth perception. However, these non-domestic kittens were slightly older than the domestic kittens tested, being between the ages of 35 and 70 days old – so it is unknown if these feline species are able to perceive depth at earlier ages. Additionally, the researchers found some differences between the *Panthera* species. Compared to the other species, snow leopards spent the longest amount of time gazing over the side of the cliff and were the only species to spend

all of their time on the shallow side of the cliff (Routtenberg and Glickman 1964). Because snow leopards are the only of these species to live in a rocky mountain habitat, this behavior may be due to differences in behavioral ecology, or differences in traits selected for in response to the environmental contingencies that species has encountered.

Similarly, as a cat navigates its environment, what it perceives is dependent, in part, on the stimuli it encountered as a kitten during the early development of its sensory systems. Several seminal experiments with the domestic cat visual system have highlighted the importance of early experience in shaping brain development and perception of the environment. For example, kittens that were reared in environments with only vertically oriented lines or, alternatively, only horizontally oriented lines, were unable to detect the alternative line orientation when tested later (Blakemore and Cooper 1970).

Cats also display flexibility in their ability to compensate for a lost sense. Blind domestic cats show more precision in locating an auditory stimulus and significantly sharper tuning of cortical neurons to auditory cues than cats with normal vision (Rauschecker and Kniepert 1994). This suggests a cat's brain can adjust in response to the loss of one sensory function by the sharpening of another modality.

Prior experience is also important in the perception of olfactory stimuli and cats appear to readily be able to distinguish between different sources of scents (for review see Vitale Shreve and Udell 2017). Normally reared domestic kittens are able to orient to their family nest region and typically show reduced distress in the presence of their family nest area. However, kittens that are initially isolated at birth from their mother and littermates, and therefore unable to learn the scent of their family, are unable to orient to their family nest region and emit distress vocalizations in response. This indicates that recognition of the family scent is dependent on experience with that olfactory cue. Adult cats also behave differently in the presence of scents from familiar and unfamiliar cats. Cats will spend significantly longer sniffing the feces or urine marks of unfamiliar

conspecifics than that of familiar conspecifics. This indicates that familiarity of the scent stimulus influences the degree of the behavioral response.

Together, research with felines, specifically the domestic cat, indicates that a fully functioning perceptual system is not only dependent on the genetic makeup of the animal but also the stimuli encountered during development of the individual.

## Learning

Skinner's (1938) influential work on the behavior of organisms would suggest significant species continuity with respect to classical and operant conditioning. Therefore, once a cat has perceived a stimulus in its environment, it is likely that similar basic learning principles apply across species. However, it is possible that variation in some aspects of learning including reinforcer preference or imitation may vary between species, populations, and even individuals.

In pioneering experiments, Thorndike (1898) placed food-deprived domestic cats in puzzle boxes in which they could escape and receive a food reward by engaging in some behavior, such as pulling a cord loop to open the door of a puzzle box. Although initially cats tended to try to escape the box through spontaneous behaviors such as clawing or biting the bars of the box or trying to squeeze through the bar slots, over repeated exposure to the box, the cat's behavior changed. Eventually, the cat may pull the cord by accident, the door to the box opens, and the cat is rewarded with both escape from the box and food. Therefore, when placed in this situation, the cat makes an association between engaging in the cord-pulling behavior and the consequences of escaping the cage (the removal of an aversive stimulus, which increases a behavior or negative reinforcement) and receiving a food reward (the addition of an appetitive stimulus which increases a behavior or positive reinforcement). These early experiments highlight the ability of cats to make associations between a behavior and a consequence, the basis for operant conditioning.

Increasingly, domestic cats are trained for entertainment outlets and to participate in discrimination tasks in scientific settings. Many zoos and sanctuaries also train captive wild felines in order to make health care procedures easier for animal caretakers and reduce stress for the felines involved. In scientific settings, domestic cats can learn to differentiate between stimuli with different characteristics, such as rectangles of varying colors, white or black, and varying orientations, horizontal or vertical (Mumma and Warren 1968). Cats can also be trained to discriminate between visual quantities of two and three groups of dots (Pisa and Agrillo 2009). Felines as a whole may have the ability to learn quantity discrimination, as lions (*Panthera leo*) also have the ability to discriminate between the vocal recordings of an individual lion compared to a group of three lions (McComb et al. 1994). However, the exact features of the stimuli being used to assess quantity in felines are unknown. For example, in dot quantity comprehension, cats could be using the spatial area covered by the dots as a discriminative cue, instead of the actual numerical values. Additionally, laboratory-reared domestic cats, which have experienced a limited range of stimuli in their environment, often display impairment on discrimination and associative learning tasks as compared to free-roaming cats, which have encountered a broader range of stimuli (Żernicki 1999). Again, this knowledge indicates that providing species-appropriate experiences, such as access to the outdoors and enrichment, is vital in increasing the welfare of felines in captivity and reducing cognitive impairment.

In tests examining what characteristics of stimuli are most salient in facilitating learning on cognitive tasks, there appear to be differences between individual cats. In one study, although the majority of domestic cats preferred use of the visual cue over the olfactory cue, one individual displayed reliable preference for the olfactory cue (Mayes et al. 2015). This finding indicates there is individual variation in what sensory cues are used in learning tasks, with this preference for one cue over another potentially shaped by that individual's prior learning experience with those cues.

Cats can also gather knowledge via observational learning, in which learning occurs by viewing the actions of another individual. In order to receive a food reward, domestic kittens had to learn to press a lever in the presence of a light, which served as the discriminative stimulus. Kittens that were able to observe their mother engaging in the task both discriminated the task and acquired the response sooner than kittens that observed a stranger cat engaging in the task. Kittens that did not observe an adult engage in the task, and were thereby left to engage with the task by trial and error, never acquired the behavioral response at the same success rate as the observational group (Norton 1974). Just like kittens, several experiments have shown adult cats can benefit from observing another individual complete the task.

It appears that not only domestic cats are capable of observational learning. Preliminary research indicates lions are also capable of social learning (Borrego 2017). Although the majority of lions were able to solve a puzzle box task independently, some were initially unsuccessful at the task. However, after the unsuccessful lions were paired with a successful lion, all but one lion was able to successfully solve the task, indicating that observation of a social companion can facilitate learning, at least in a social species. To date, no one has examined the observational learning abilities of an asocial feline species. However, with social interactions still occurring in asocial species, especially during mating and kitten rearing, social learning may still be an important aspect of learning in more solitary species, especially during early interactions with the mother and littermates.

## Social Cognition

Social cognition is one of the most understudied areas of feline cognition. One reason for this disconnect may in part be due to the misconception that felines are not especially social. Instead, research from free-roaming cats indicates that social living in domestic cats is flexible and dependent on both life experience and the

distribution of food, shelter, and mate resources (Bradshaw and Cameron-Beaumont 2000; Turner 2014). Domestic cats are a facultatively social animal, meaning they can live socially or solitarily, and therefore display a wide range of nonobligatory social behavior toward conspecifics and humans. Additionally, although only two other feline species, lions and cheetahs (*Acinonyx jubatus*), commonly live in social groups, other asocial species still engage in social behavior with one another during breeding, kitten rearing, and territorial defense, and much of this social behavior has gone unstudied (Elbroch et al. 2017).

Because of the ability of cats to discriminate between stimuli in the environment, it is no surprise domestic cats can discriminate between both conspecifics and humans. Free-roaming cats have preferred associates within the colony, or individuals a cat prefers to spend time near and displays affiliative interactions toward (Crowell-Davis et al. 2004). This indicates that domestic cats can not only differentiate individual conspecifics within a colony but also form social relationships with certain individuals over others. Similarly, lions, which form socially complex associations with one another, also have this ability. Male lions are able to differentiate between roars produced by males and females, and female lions are able to discriminate between roars of familiar resident males and unfamiliar males (Borrego 2017). Overall, it appears that felines, at least social species, have the capacity to differentiate between conspecifics.

Domestic cats also appear to behave differently in response to familiar and unfamiliar humans. Behaviorally, cats display a significantly higher body orienting response (movement of ears and head) to their owner's voice compared to a stranger's voice (Saito and Shinozuka 2013). Physiologically, cats exhibit significantly higher blood pressure rates in the presence of their owner compared to an unfamiliar human, which in other species has been suggested to indicate anticipation of interaction with a bonded individual (Slingerland et al. 2008). However, some studies have found that domestic cats spend more time in association with an unfamiliar human, indicating

that familiarity is not the only mechanism influencing social behavior; novelty may also be a factor (Podberscek et al. 1991).

Humans provide a variety of attentional, emotional, and gestural cues during interaction with cats, and research has begun to explore the sensitivity of domestic cats to these cues. One such study examined how cats behaved in the presence of an unfamiliar human who was either sitting passively, ignoring the cat and reading a book, or interacting freely with the cat. Cats displayed more social behaviors such as allorubbing and playing during the interactive phase, indicating the attentional state of the human can directly influence the social behavior of cats (Mertens and Turner 1988).

More recent research has examined if pet cats can detect the emotional state of a human and adjust their behavior in response. Using a social referencing paradigm, the cats are placed in the presence of an unfamiliar, potentially frightening stimulus, often a desk fan with streamers attached. The cats are then exposed to one of two human emotional groups, with some cats experiencing their owners providing a positive emotional message toward the fan and the other cats experiencing a negative emotional message to the fan. Cats were found to gaze at their owner's face and the unfamiliar stimulus at similar rates found in domestic dogs and also adjusted their behavior in response to their owner's emotional message to some extent. Cats in the negative group more frequently gazed at the room exit (the only way out of the room), were active and more quick (potentially preparing for escape), and interacted with their owner more frequently (potentially indicating security-seeking behavior) than cats in the positive emotional group (Merola et al. 2015).

Further evidence that domestic cats are sensitive to human cues has come from research that presented cats with human facial, postural, and vocal cues that expressed happiness or anger from both an unfamiliar human and their owner. Although the researchers found cats were not sensitive to the vocal cues and were only moderately sensitive to the visual cues, they found cats were most sensitive to the happy visual cues given off by their owner and were significantly more

likely to interact with their owner when they displayed happy visual cues over angry cues, although no difference was seen with the unfamiliar human (Galvan and Vonk 2016). Cats also appear to be proficient in following pointing gestures, another physical human cue, and are able to follow human pointing to successfully find the location of a food reward (Miklósi et al. 2005). Overall, domestic cats seem to be able to pick up on human cues and adjust their behavior to some extent, although the familiarity of the human providing the cues, and possibly the reinforcement history of the cues given off by this individual, may influence the degree to which cats pick up on these cues.

Cats appear to be able to use gazing at the owner's face as a way to pick up social information and adjust their behavior accordingly. However, cats may use gazing differently depending on the situation presented. For example, when presented with an unsolvable food task, cats persisted and engaged with the task for longer periods of time and infrequently gazed at their owners, as compared to dogs that gazed at the owner earlier and for longer periods of time (Miklósi et al. 2005). Therefore, cats may use gazing in social situations, such as when presented with an ambiguous stimulus or using physical human cues, but may be less likely to gaze at the owner for help on tasks involving physical problem solving.

What happens when non-domesticated feline species encounter humans? As would be expected, non-socialized big cats do not have the same response to humans as a domestic cat. Although understudied, preliminary research indicates that big cats kept in captivity are more stressed when they see human visitors through their enclosure. However, affiliative behavior toward humans can be seen in socialized, non-domesticated *Felidae* species. Researchers found several socialized *Felidae* lineages, including the domestic cat, caracal, lynx, and ocelot lineages, display affiliative behavior such as allorubbing, licking, and tactile contact toward zookeepers (Cameron-Beaumont et al. 2002). Interestingly, the highest proportion of affiliative behavior came from the ocelot lineage, which diverged

from the domestic cat lineage millions of years ago. This indicates that *Felidae* as a whole may have a preadaptation for domestication if other environmental criteria are met.

Finally, the individual characteristics, or personality, of a cat may influence the way they behave toward social companions. Personality can be defined in many ways, but broadly it is a prolonged state in which behavioral responses are relatively stable over time and circumstances (Gosling 2001). Many scientific studies have indicated domestic cats do indeed display relatively consistent behavioral patterns, with individual differences between kittens within a litter being detected as early as 5 days old and behavioral patterns stabilizing around 3–5 weeks old (for review see Vitale Shreve and Udell 2015). Indeed, the individuality of the cat is one of the largest factors influencing how they behave socially with humans (Mertens and Turner 1988). Cat personality is influenced by a combination of both genetics and life experience; therefore domestic cats exist on a continuum of social cognition.

Research with lions has also demonstrated individual variation within the species, finding substantial variability in how lions respond to conflict. When presented with the roar of a possible intruder, female lions behave in various ways, with some females consistently cooperating and other lions only cooperating when it is absolutely necessary (Heinsohn and Packer 1995). Additionally, this behavioral response appears early in life and persists into adulthood, indicating it is a relatively stable behavioral pattern and thereby potentially an aspect of lion personality.

This individuality of domestic cats in response to humans can be seen in a recent study examining the preferences of cats. Cats underwent a preference assessment in which they were placed with several categories of stimuli – items in human social interaction, food, toy, and scent categories. Individual cats displayed a range of preferences within these categories. Some cats most preferred to be pet in the human interaction treatment, whereas others most preferred playing, while again some did not prefer the social stimulus at all. For each category cats displayed a range of preferences, forming a list of most preferred items

unique to each individual (Vitale Shreve et al. 2017). This research indicates that individual variability for preferences exists in cats and, just like personality, is most likely due to a combination of genetic, experiential, and motivational mechanisms. Additionally, in a final treatment, where each individual cat's most preferred social interaction, food, toy, and scent item were presented simultaneously, the majority of cats displayed a preference for the social stimulus – even when presented with their most preferred food, toy, and scent item, thereby foregoing interaction with those items. The next most preferred category was food, followed by toys, then scent. Again, this research suggests that preference for social interaction may lay on a continuum, but does the sociality of an individual influence any other cognitive abilities?

Although not well studied, research indicates that the sociality of a species may indeed influence their cognitive abilities. Several feline species and one non-feline species were compared on their ability to solve a puzzle box task. Researchers found that lions and spotted hyenas (*Crocuta crocuta*), both social species, outperformed leopards (*Panthera pardus*) and tigers, asocial species. Although the puzzle box task did not contain a social component, it may be that sociality influences the cognition of a species (Borrego 2017). Future research could utilize the facultative nature of the domestic cat, which exists in both solitary and social states, to further examine this hypothesis and assess if sociality has a direct influence on cognitive abilities such as problem solving tasks.

## Conclusion

With domestic cat ownership growing every year, it is no surprise that more research is being conducted on their cognition in the recent years. However, there is still much to learn about how cats of all species sense and learn about the world around them and decide to act upon the individuals and experiences they encounter. Not only will future research provide more information as to the cognition of the cats we share our homes with; comparisons of domestic and non-domestic feline

species may also address the extent to which domestication alters the cognition of a species and how living socially or solitarily influences other aspects of cognition.

## Synonyms

Cat communication

## Definition

Cats communicate by visual, vocal, olfactory, and tactile signals. Among carnivores, cats are considered as relatively less social, but they still have a rich signaling repertoire. They communicate directly in social contact, as well as by leaving long-term messages. Domestic cats have to communicate efficiently with conspecifics as well as with human caretakers.

## Introduction

Domestic cats (*Felis catus*) are solitary hunters, but, at the same time, they have a potential to live as social animals. Therefore, cats have flexible social behavior like other carnivores (Macdonald 1983). Indeed, a human-made environment provided cats with ample and secure food resources, so, during domestication, they started to live at higher densities, unlike their ancestral species (*Felis silvestris lybica*), which are solitary animals. By entering human settlements, the cats formed groups with high intraspecific tolerance. These changes in the social organization and group density led to an evolutionary change in the communication system used by the domestic cat. Indeed, solitary and group-living individuals may choose different modalities of communication (Bradshaw and Cameron-Beaumont 2000). Furthermore, the relationship with humans has generated additional communication signals specific to cat-human interactions (Crowell-Davis 2005). Cats can communicate their mood and intention (Crowell-Davis 2005). Information can

be conveyed as visual, vocal, olfactory, and tactile signals (e.g., Beaver 2003; Bradshaw and Cameron-Beaumont 2000).

## Vocal Communication

The domestic cat is one of the most vocal carnivores (Bradshaw 1992; Crowell-Davis et al. 2004). Vocalization may be partly inborn and partly developed by auditory feedback that cats get through ontogenetic development (Hubka et al. 2015). In home-raised cats, Moelk (1944) described 16 different voice patterns and divided them into three main categories with relation to the mouth opening. The first category is “murmurs,” i.e., sounds produced while the mouth is kept closed. The second category is “vowel-patterns” – sounds produced while the mouth is opened and then slowly closed. The third category includes sounds produced while the mouth is opened in a constant position (Beaver 2003; Moelk 1944).

“Murmur” patterns are generally considered as indicators of a friendly or relaxed emotional state and contentment, because they include acknowledgment, call, grunt, and purr (Beaver 2003; Stanton et al. 2015). However, cats can purr in any conditions, pleasant and unpleasant, and in many different contexts, such as when they are happy, content, or aroused. Therefore, purr may be related to high emotional arousal, regardless of situation (Casey 2007).

Cats purr when they are petted by their owners, when they are rubbing against an object, rolling on the ground, or when falling asleep. Furthermore, the queen is purring during nursing, and a purr is a part of a friendly greeting and care-soliciting call. Hence, in these cases, the purr can be considered as a sign of contentment. On the other hand, cats will also purr when they are distressed or in pain, such as during birth or before death following a chronic disease, so maybe the purr has a self-soothing and healing function (Casey 2007; Crowell-Davis 2005).

Finally, sometimes cats purr while they are trying to seek something from their owners, e.g., food, attention, or access to the outdoors. This is called a solicitation purr, and it sounds more like

cry: it is lower pitched, harsher, and quicker or more urgent, so it differs from the natural low-pitched purr (McComb et al. 2009).

The purr is unique to the family Felidae. While purring, domestic cats are able to produce between 25 and 150 vibrations per second. Depending on the context, purrs have different forms. Cats purr during inhalation and exhalation, but the inhalation sound is usually louder, longer, and a lower-pitched component of the purr (Beaver 2003; Case 2010).

“Vowel patterns” are the second group of sound produced by cats. They are produced when the cat’s mouth is first open and then slowly closed. According to Beaver (2003), “vowel patterns” are anger wail, bewilderment, complaint, demand, mating cry produced by estrus females, Siamese vocalizations, and ultrasonic variations. These sounds are more articulated and are related to particular situations such as those involving goal-seeking or frustration with goal seeking, as well as when a cat is soliciting the help of the owner (Moelk 1944).

The third group is the “strained-intensity patterns,” which are vocal patterns produced with the mouth open. “Strained-intensity patterns” are growl, hiss, mating cry of a tomcat, refusal, scream, and snarl (Beaver 2003). They are noisy and expressed in intensely emotional circumstances, such as when a cat is nervous, angry, ready to attack or withdraw, and as a mating demand. In dockyard cats, females in estrus were not heard to call but toms that were seeking estrus females emitted a characteristic cry (Dards 1983). They may be expressed in aggressive confrontations, such as growls, yowls and snarls, or in defense, such as a hiss and a spit (Casey 2007).

Vocal communication is very important for mother-kitten relationships. Kittens can distinguish their mothers’ vocalization, “greeting chirps” and “meows,” from the vocalization of other cats by 3 weeks of age (Szenczi et al. 2016). On the other hand, kittens use several special calls that diminish as they get older, and the mother responds to these calls by a chirp kind of trill. Therefore, certain vocalizations are responsible for maintaining connections between them (Casey 2007).

Interestingly, cats living in feral colonies tend to be much quieter than domestic cats but can be loud during breeding season. Shimizu (2001) described three distinct types of vocalization in feral cats: rutting cry, yowl, and mew. The rutting cry can be heard only in breeding seasons, and it is frequently produced by males. Furthermore, in laboratory cats, which are less socialized with humans, the vocal repertoire is extremely limited (Rosenblatt and Schneirla 1962).

It is therefore considered that the meow is something that cats mostly use to communicate with humans and not for communication with other cats. As every cat learns the best way to communicate with its owner, huge individual variations can be observed in vocalizations. Cats' vocalizations towards their owners are shaped by operant learning, so the cat will adapt the sound that works best on their owner (Casey 2007). Domestic cats do not have a context-specific repertoire of human-directed vocalization as such, but cat owners with experience can become successful in context classification of their cats' meows (Ellis et al. 2015; Nicastro and Owren 2003). When vocalizing, cats vary their intonation to indicate different emotions, and humans can distinguish them based on signals used to express emotions in human speech (Schötz 2014).

In comparison of meow vocalizations by domestic cats (*Felis catus*) and African wild cats (*Felis silvestris lybica*), human listeners considered domestic cat meows as more pleasant sounding than wild cat vocalizations, what may be considered as a consequence of domestication pressure on meows from people (Nicastro 2004).

Finally, being more or less vocal is a part of a cat's personality (Litchfield et al. 2017). However, some cat breeds are a lot more vocal than other cats, as for example, oriental breeds, such as the Burmese and Siamese (Beaver 2003; Landsberg et al. 2003).

## Olfactory Communication

For cats, communication with odor means leaving long-term messages with urine, feces, by scratching and by rubbing alongside their body,

as well as direct smelling of another cat (Bradshaw and Cameron-Beaumont 2000). Cats have an excellent sense of smell and the capacity of cats' olfactory communication is still not fully understood (Crowell-Davis 2005). Furthermore, general body odor is important for mother cats to recognize their kittens from others (Bánszegi et al. 2017).

Having a solitary wild ancestor, domestic cats still have evolutionarily driven motivation to defend and demarcate the hunting territory. They mark the boundaries of their territory with their scent in the form of urine and feces, as well as by scratching to leave scent from interdigital glands (Crowell-Davis 2005). For solitary animals, remotely messaging by scent-marking is an important aspect of their behavior because they can maintain distance between each other. Furthermore, it permits a delay of several hours or days between the deposition of the signal and its reception. In this way, they can maintain the territory without the risk of potentially dangerous encounters and conflicts with conspecifics (Bradshaw and Cameron-Beaumont 2000; Casey 2007).

Olfactory messages are left in prominent places or places where other cats are expected to pass. These messages can have different meanings to the recipient animal, such as which individual left the scent, particularly with regard to reproductive status and, possibly, the emotional state of the signaler, and the time when the message was left (Casey 2007; Crowell-Davis 2005).

Cats can urinate in two different postures, one is when they squat and the other is when they intentionally scent-mark by spraying. After urination in squatting position, cats cover the urine with soil or litter, but other cats may still sniff it. Squatting is observed in kittens, juveniles, and adult females (Bradshaw and Cameron-Beaumont 2000; Case 2010).

Spraying behavior is mainly used by intact male cats as sexual marking behavior but is naturally performed by all cats, regardless of their gender and sexual status. When a cat is spraying, it backs up to a vertical object, and urine pulses backwards, while its tail is raised and quivering. In this way, cats mark their home range, especially

on pathways, crossings, and boundaries, and leave a scent message to other members of their social group, cats from outside the group, but also for itself (Bradshaw and Cameron-Beaumont 2000; Casey 2007; Crowell-Davis 2005).

When cats are kept permanently inside the house, urine spraying may occur as a sign of social conflict among cats or as a sign of stress and anxiety. Cats can be in conflict with the cats in the same home in a multiple-cat household or with outdoor cats that walk and spray around the house. In cats, stress and anxiety can be caused by some environmental changes, such as when owners are moving house, having a new baby, or are visited by some guests (Case 2010; Landsberg et al. 2003). Therefore, for cats, chemical cues can serve as a coping strategy because they can reduce stress and anxiety as well as increase feelings of self-assurance. When an individual cat leaves messages for herself, scent marks could be a reminder of something unpleasant or make her feel more secure in her environment (Casey 2007; Vitale Shreve and Udell 2017).

Therefore, spraying behavior is a complex signal, where the scent is left as a long-term signal, while display can be a visual signal meant to draw attention of others. Cats show a great interest for urine marks left from other cats and investigate it by sniffing (Bradshaw and Cameron-Beaumont 2000). When cats smell the urine mark of another, they are not intimidated and they do not tend to cover it with their own scent, and they spend a lot of time investigating the smell of urine of unknown individuals (Beaver 2003; Case 2010).

The odor of sprayed urine is strong and sharp and consists of different chemical compounds. Maybe the two most important compounds are feline and isovalthene, whose microbial and oxidative degradation increase odor after deposition. Intact male urine odor is stronger than that of females, and it changes with age (Bradshaw and Cameron-Beaumont 2000). However, the chemical composition of urine can differ, so the urine may not always be giving the same signal. For example, it may comprise different pheromones, which are deposited in the spray mark, and this may vary with the emotional state of the signaler (Casey 2007).

Before defecation, domestic cats dig a small hole, and afterwards they bury the feces. However, occasionally they may leave feces uncovered at certain locations probably as a territorial marker for another cats (Crowell-Davis 2005; Macdonald et al. 1987).

Rubbing behavior is another way in which cats use scent marks. They rub against other individuals, cats, or human companions, and different objects. Cats have scent producing glands on their skin: enlarged sebaceous glands at the corners of the mouth, on the chin, temporal glands on the side of the forehead, in the ear canals, in the perianal area, at the base of the tail, and all along the length of the tail (Beaver 2003; Case 2010). When cats are rubbing (or bunting) against others, such behavior suggests a social relationship. Cats like to rub against others, as well as when they are stroked on the gland areas – and deposition of odors on others suggests friendly relationships (Crowell-Davis 2005). Cats sometimes purr when they are rubbing their heads on each other or against human companions, so this may also be a composite signal.

Furthermore, object rubbing is how cats deposit and pick up some scents. Specifically, head rubbing (bunting) seems to happen in the core areas of a cat's territory, performed on the visually prominent objects. This behavior seems to be highly correlated with comfort activities, the solicitation of social attention, and positive emotional state (Bradshaw and Cameron-Beaumont 2000; Casey 2007).

Scratching is another composite signal that has multiple functions for cats, where they leave scent marks from the glands in the paws. Additionally, the resulting visual signal includes leaving long-term scratches on the surface of trees, fences, sofas and other furniture, as well as on special cat scratching posts (Case 2010). In general, scratching is very important for cats because it allows them to trim their claws, to stretch front legs, shoulders and back but also to exercise the muscles and tendons involved in claw protraction and retraction, which they need for hunting (Casey 2007). Cats may scratch horizontal or vertical surfaces

that have a rough texture, such as wood bark or heavy cloth, and they frequently use the same site (Case 2010; Crowell-Davis 2005).

## Visual Communication

Living in social groups places an additional evolutionary pressure on cats to communicate more by visual signals given by body positions and movements. However, cats are solitary predators, so they lack the complex visual signaling repertoire that can be seen in social predators. In comparison with some other carnivores (e.g., wolves), cats have immobile flat faces, with less facial muscles that enable subtle changes in expression. Furthermore, the coloration of cats' fur is not specifically adapted for signaling (Bradshaw and Cameron-Beaumont 2000).

Cats can use several communicative body postures for maintaining harmony in a social group, but they are probably less important for the cat than for more social animals (Beaver 2003). They have a capacity to communicate some emotions to each other and to human companions. Their visual signals may include the orientation of the cat's whiskers and ears, the size of a pupil, a position and movement of the tail, and the whole body posture. Having limited body language to a certain degree, cats do not have a range of appeasement signals for resolving the social conflict, so they tend to display either defensive or offensive aggression or avoidance when faced with aggressive individuals (Case 2010; Casey 2007).

Facial expressions in cats are subtle, but it can be estimated how the cat is feeling by paying attention to the eyes, ears, and whiskers. The ears and whiskers will be pointed forward when the cat feels friendly and when she is interested in a particular person or an object. However, if the cat feels scared or threatened, her ears will be pressed back and down, while the whiskers will be pulled back. When cats are frustrated or angry, their ears are pulled backwards and the whiskers can be protruded from the face (Beaver 2003; Bradshaw and Cameron-Beaumont 2000).

The cat's eyes can also signal pleasure or agitation. For example, relaxed cats may softly gaze with their eyes half closed and slow blinking eyelids. On the other hand, when the cat is anxious, fearful or highly aroused, her pupils will be dilated. Cats can perceive direct gaze as a threat, and therefore, gaze aversion is a signal that a cat is avoiding a conflict. Constricted pupils are a signal that a cat feels tense and potentially aggressive (Case 2010).

In agonistic encounters, cats may display offensive or defensive threat and fear. Additionally, cats can experience conflicting emotions, such as fear and anger at the same time, and then it is more possible that they will show the arched body posture. Some postures adopted by a cat can be considered as the cat's efforts to look bigger. An aggressive, attacking cat in offensive threat will stay in full height, with a rigid body posture, piloerected coat, straightforward view, and the tail is up. In defensive threat, the cat will turn side-on to the opponent, with arched back, ears flattened back, bared teeth, and wrinkled nose (Beaver 2003). On the other hand, a fearful cat that wants to withdraw from an agonistic encounter will crouch on the ground, have a low and tucked body posture, and flattened ears (Bradshaw and Cameron-Beaumont 2000). Offensive and defensive threatening cats can be described as "active responders," while fearful individuals are "passive responders" (Casey 2007).

A relaxed and content cat may stretch out, lie on its side with visible tail, but it may also roll over and expose its abdomen as a sign of trust. By rolling on its side or back, cats expose abdomen, i.e., the most vulnerable part of their body (Beaver 2003). In addition, cat may expose its belly to solicit play by their owners, when rolling to rub its back on a ground or as a part of aggressive display (Case 2010; Stanton et al. 2015). While Crowell-Davis et al. (2004) consider rolling over as submissive behavior, Case (2010) states that this is learned behavior and not sign of submission.

In visual communication, the tail postures and movements can be important for sending a message. In fact, the tail may be the most expressive part of the cat's body and the easiest one for

humans to read (Casey 2007). A usual tail position is roughly flat. An arched tail or inverted-U posture tail may be seen during aggressive encounters or conflicts, while an anxious or fearful cat will lower and tuck the tail closely in between her legs or around its body (Beaver 2003).

In greetings and friendly encounters, the cat will raise the tail vertically. The tail up is displayed when an adult individual meets another one as a “friendly” signal (Cafazzo and Natoli 2009; Casey 2007). Furthermore, kittens greet their mother and other adult individuals in this way. The whole greeting behavior with tail up of kittens, including rubbing their forehead and then upper part of the head against mother’s chin, may be considered as a display that should inhibit the potential aggressiveness of adult cats. Additionally, during domestication, this juvenile behavior might have been conserved in the adult cats (neoteny) to inhibit aggressive encounters because of the increased number of social interactions (Cafazzo and Natoli 2009).

The movement of the tail can also be very expressive and quite subtle, too. When a cat is flicking tail, she is signaling that she is in uncomfortable situation. An angry cat will thrash with a tail, while a swishing tail will be seen in a cat that is frustrated. The function of the twitching tip of the tail is still not fully understood (Casey 2007).

## Tactile Communication

This form of communication is important for feral cats of the same colony and can be observed in cats from the same household as well. Tactile communication includes resting together (lying or sitting together), allorubbing (cat-cat rubbing their heads, flanks, or tail), allogrooming (one cat licking another), nose touching, or a simple tail contact (Bradshaw and Cameron-Beaumont 2000; Van den Bos 1996). Furthermore, cats use their tails to stroke each other or wrap their tails together. This may enhance social bonding and social harmony within a group (Crowell-Davis et al. 2004).

When allorubbing, cats wipe their heads, bodies, and tails against each other and repeat this for several minutes. It is speculated that this behavior has multiple functions. Because allorubbing cats often purr, this behavior may have social significance similar to human hugging. Furthermore, in this way, cats exchange their scent, which may be important for group cohesion (Barry and Crowell-Davis 1999).

Allogrooming can be observed in cats, where in indoor cat colonies, usually individuals that are more aggressive groom less aggressive individuals more frequently (Van den Bos 1998). On the other hand, Barry and Crowell-Davis (1999) observed indoor-only altered domestic cats, and they did not find differences in this behavior display in cats of different gender, between household types, or between recipients of the affiliative behaviors.

Finally, it is important to notice that most of the communicative signals are in fact composite, and their meaning should be explained in the context of all body signaling. Indeed, animals have the flexibility to combine signals in patterns that carry particular meaning. For example, when different body postures are explained, they may include signaling by ears, eyes, and tails, while this body display is accompanied by a vocalization and the odor of the whole body. Similarly, scratches are obvious composite signals with a visual and olfactory message.

## Feline Behavioral and Welfare Problems Due to Incomplete Understanding of Communication

There are several behavioral problems that cat owners report and that are related with cat communication. However, more important is the influence on cat’s welfare because sometimes people relinquish their cats to shelters or they simply leave them on a street. It is particularly sad that some of the complaints are due to the cat’s normal behavior, such as scratching. In some countries, it is still permissible to declaw cats to stop furniture destruction (Beaver 2003). Because scratching is important for cats as a visual and olfactory signal, such a procedure has to reduce cats’ welfare.

Sometimes cats are accused of aggressive behavior toward humans, while owners do not understand and appreciate the cats' communicative signals, such as tail flicking, the way cats signal that they are uncomfortable with a situation, and that the owner needs to retreat. On the other hand, cat-cat aggression occurs because humans dictate which cats have to live together.

Moreover, leaving "pee-mails," i.e., spraying vertical surfaces, is a behavior that cats use to communicate between each other but also to make it easy for themselves when they are stressed (Vitale Shreve and Udell 2017). However, cats' urine has a pungent smell for humans and may be the reason why some cats lose homes or are even euthanized. This problem behavior may be more frequent in Bengal and Birman cat breeds, while it is less present in Maine coon cats (Wilhelmy et al. 2016).

Finally, some cats may vocalize extensively, which is also considered a nuisance for pet owners. Because this is more frequently present in oriental breeds, the breed standards should be reconsidered to reduce the problem. In Tonkinese cats, this behavioral problem is more prominent, and less present in Abyssinian and Birman cats (Wilhelmy et al. 2016). Finally, increased vocalization occurs most commonly in elderly cats and can be a symptom of some physical illness (Landsberg et al. 2003).

## Conclusion

Cats have made an extraordinary adaption from solitary animals that mostly used distant communication signals, to social group members that are able to exchange information in close proximity. They have also succeeded to develop a communication catalogue for humans, as well as for other animals that they have to live with in human households. However, human beings can probably comprehend the meaning of vocal and visual signaling, but olfactory communication is often overlooked in cat-human communication. Future research may bring more understanding and consequently higher quality of life for domesticated cats.

## Feline Diet

Brittany D. B. Greene  
Independent Researcher, Suffolk, VA, USA

## Synonyms

Cat diet

## Definition

The necessary foods commonly eaten to provide nourishment and sustenance specific to species within family Felidae.

## Introduction

Forty-one extant felid species exist today, grouped within two subfamilies of the Felidae family: *Pantherinae* and *Felinae* (Kitchener et al. 2017). These species possess a multitude of physical

characteristics, each combining into a singular morphology that is considered similar among all cats. Many shared physical characteristics among felids can be attributed to an overall morphology adapted and evolved for hunting to meet the specialized hypercarnivorous diet which all cats thrive upon (Sunquist and Sunquist 2002). Individuals within felid species require a much higher percentage of diet from protein and possess a morphology that reflects an ability to hunt, capture, and kill live prey (Sunquist and Sunquist 2002).

Though a singular morphology exists as a result of diet similarities in felids, felid species also exhibit distinctive diet differences. As sea levels dropped and land bridges appeared millions of years ago, ancestral individuals of modern-day felids dispersed and emigrated from Asia to other continents (O'Brien and Johnson 2007). These migrations allowed for the formation of new lineages in which individuals could adapt to new environments and, over time, evolve into today's existing unique felid species (O'Brien and Johnson 2007). As a result, felid species vary in size and are exposed to differing prey options, both of which have allowed for the establishment of variations in diet.

## Diet Nutritional Requirements

Although numerous carnivorous felid species exist, most research on dietary nutritional needs have been conducted on the domestic cat, *Felis catus* (Howard and Allen 2007; Morris 2002). Therefore, nutritional requirements for diets composed of commercially prepared raw-meat diets for captive nondomestic felid species are determined utilizing information previously studied and discovered regarding domestic cats (Howard and Allen 2007). The nutritional information gleaned through studies of the domestic cat has proven successful in providing the necessary nutritional requirements for captive nondomestic felid species (Howard and Allen 2007). For the purposes of this entry, the general nutritional requirements determined to date for domestic cats will be discussed and applied for all felid species.

Felids are “obligate,” or “strict,” carnivores, meaning they require meat in order to survive (Case et al. 2011; Gates 2019). The felid diet must be primarily composed of high-protein meat due to nutritional requirements that can only be satisfied through consuming animal tissue (Case et al. 2011). The highly specific nutrient requirements of the high-protein meat diets felids consume are believed to have evolved as a result of adaptations due to evolutionary pressures acting upon metabolic enzymes in cats (Morris 2002). Eisert (2011), however, postulated that the high-protein nutritional requirement noteworthy in hypercarnivorous felid diets may actually be a secondary phenomenon. Eisert (2011) hypothesized that the required diet in felids may be the result of high glucose demands from high glucose-requiring tissues, including the brain, that is fulfilled using amino acids supplied by protein to synthesize glucose through a process known as gluconeogenesis.

Aside from the high-protein requirement that only animal tissue can satisfy for strictly carnivorous cats, felids also require multiple nutrients that can only be obtained from animal sources due to an inability to synthesize such nutrients (Case et al. 2011; Morris 2002). These nutrients include arginine, taurine, water-soluble B vitamins, vitamin A, vitamin D, and arachidonic acid (Case et al. 2011; Morris 2002; Zoran 2002). Arginine, an amino acid necessary in the urea cycle, is considered a highly essential nutrient in the felid diet, with the lack of arginine in a single meal observed to induce hyperammonemia, acute ammonia intoxication, and hyperglycemia in cats, resulting in swift death (Morris 2002; Morris and Rogers 1978). Taurine, a highly studied amino acid in the felid diet, is necessary for bile salt formation and must be obtained by felids from outside dietary sources due to an inability to endogenously produce sufficient amounts (Howard and Allen 2007). Water-soluble B vitamins, including niacin, thiamin, and pyridoxine, are unable to be stored in the body and must be continuously supplemented using diet as well (Zoran 2002).

Necessary for healthy vision, skin, bone growth, and reproduction, vitamin A can be

converted into its active form from carotenoids, such as beta-carotene, in plants using an enzyme found in the intestines of certain animal species (Case et al. 2011). As felids do not possess this specific enzyme, referred to as beta-carotene 15,15'-dioxygenase, they are unable to convert plant-based carotenoids into vitamin A and therefore require animal-based dietary sources that can supply preformed active vitamin A (Case et al. 2011; Lakshmanan et al. 1972). Vitamin D, important for well-balanced calcium and phosphorus within the body, is also required from dietary sources for felids due to an inability to synthesize the vitamin endogenously (Morris 2002; Zoran 2002). Aside from fat providing energy and food palatability for felids, essential fatty acids, such as linoleic acid and arachidonic acid, are crucial for skin and coat condition, kidney function, and reproduction (Howard and Allen 2007). Unlike most animal species, felids lack sufficient activity of necessary enzymes for converting the essential fatty acid known as linoleic acid into a necessary essential fatty acid known as arachidonic acid, though they can obtain it from animal sources as well (Howard and Allen 2007; Zoran 2002). Felids are capable of meeting dietary requirements for arachidonic acid, vitamin A, and vitamin D through the consumption of animal fats which contain ample amounts of each (Case et al. 2011; Zoran 2002).

## Form of Diet

To satisfy the high-protein, obligate, hypercarnivorous diet composed almost solely of meat with the highly specialized nutritional requirements discussed above, felid species eat food in several different forms. Domestic cats are typically fed commercially produced dry foods, though a canned-food or even raw-meat diet has been advocated for in recent years due to negative health effects that have been associated with eating a commercial diet (Bernard 2004; Pierson 2013). As previously noted, captive nondomestic felid species, housed in North American zoos, are typically fed frozen or canned commercially prepared raw-meat diets, composed of horse or beef,

and enhanced nutritionally with vitamin and mineral additives, though some captive felids are also fed supplemental meat diets composed of skeletal muscle meat from horse, beef, deer, or turkey, and added vitamins (Bechert et al. 2002; Howard and Allen 2007). In contrast, "whole-prey diets," sometimes used in zoos and composed of carcasses, provide a well-balanced diet that more closely resembles the diets of wild felids (Howard and Allen 2007). The commercial diets mentioned above are nutritionally similar to consuming whole prey; however, captive felids eating whole-prey diets and wild felids eating whole prey are also exposed to hide, hair, and hooves that their captive counterparts eating commercially prepared diets are not (Howard and Allen 2007).

Felid species hunt a variety of prey as a result of differences in size and environmental location. For example, leopards (*Panthera pardus*) located in Africa typically hunt prey including young wildebeest, impala, varying small antelope species, warthogs, young baboons, small animals, and small birds (Fraser 2012). In contrast, snow leopards (*Panthera uncia*) found in Asia typically prey upon blue sheep and ibex and unlike other felid species will eat carrion (Fraser 2012). A smaller species comparatively to both leopard species previously mentioned, the bobcat (*Lynx rufus*) located in North America primarily hunts hares, rabbits, and occasionally small domestic livestock (Fraser 2012). As shown by the abovementioned species, the diet spectrum ranges greatly among felids due to the respective environment and prey that each species is exposed to.

## Diet Preferences

Multiple studies have found nutritional profile to be a large determining factor, potentially even over taste, when felids choose foods to eat or include in their diets (Watson 2011). When given dietary choices, felids have shown preference for fat- and protein-rich foods comparatively with foods of lower fat and protein content and also avoided diets high in casein (Beauchamp et al. 1977; Cook et al. 1985). Similarly, Hewson-

Hughes et al. (2011) noted that felids can regulate macronutrients within their diets, consistently seeking out food combinations equating to a daily intake of 420 kJ (kilojoules) of protein, 280 kJ of fat, and 100 kJ of carbohydrate, or 52% protein, 36% fat, and 12% carbohydrate, when provided with various wet and dry foods (Hewson-Hughes et al. 2011). Hewson-Hughes et al. (2011) also noted a “carbohydrate intake ceiling” in which cats would restrict dietary intake of carbohydrates to a maximum of approximately 300 kJ per day.

However, dietary preferences are not only affected by nutritional profile as olfactory and gustatory sensing impact food preference as well. Felids partially rely upon both taste and smell for determining what food to ingest or if the food is considered ingestible (Fraser 2012). Not unlike numerous other species within Carnivora, the taste buds of a felid, located on the frontal portion of the tongue, show no preference for carbohydrate sweeteners due to genetics resulting in a lack of sweet taste receptors (Beauchamp et al. 1977; Fraser 2012; Jiang et al. 2012; Li et al. 2006). This lack of sweet taste receptors is also hypothesized as one of the reasons felids are strictly carnivorous (Li et al. 2006). Though lacking in sweet taste receptors, cats, specifically housecats, have been found to prefer ingesting some amino acids over others, especially avoiding those with mildly bitter to strongly bitter flavors (White and Boudreau 1975). Even with housecats likely discerning bitter taste differently than that of humans, this is likely as a result of the bitter taste receptors housecats possess (Lei et al. 2015; Sandau et al. 2015).

## Diet-Related Health Issues

A strong link exists between diet and the development of health issues and related health diseases in felids. As noted above, specific nutritional requirements exist for felids that must be met for prime health. For example, arginine, taurine, water-soluble B vitamins, vitamin A, vitamin D, and arachidonic acid must be consumed through dietary sources for a felid to remain healthy (Case et al. 2011; Morris 2002;

Zoran 2002). Without the inclusion of the abovementioned nutrients, various important bodily functions would be unable to be performed in felids and are therefore extremely important for survival. As previously mentioned, diets without arginine were observed to produce rapid death after ingesting a single meal without the nutrient (Morris and Rogers 1978). A diet low in taurine is associated with cardiomyopathy, retinal degeneration, and reproductive issues in felids (Hayes et al. 1975; Pion et al. 1987; Sturman et al. 1987). As is apparent from the issues noted from the lack of a few of the above nutrients, diet can have huge impacts on felid health through nutrient exclusion.

Beyond the inclusion of necessary nutrients, certified veterinarian Lisa Pierson (2013) noted that diet is believed to both impact and help manage such diseases as diabetes, kidney disease, cystitis, bladder/kidney stones or crystals, urethral blockage, inflammatory bowel disease, obesity, hepatic lipidosis (fatty liver disease), dental disease, and even feline asthma. Commercially produced dry cat foods are believed by some to be detrimental to the health of cats due to high plant-based protein content unable to supply the correct nutrition for cats, high carbohydrate levels in the food that cats are not adapted for, and low water content (Pierson 2013). Domestic cats, as a result of ancestry, are adapted for dry desert environments and are also adapted to acquire most of the water in their diets from prey, making water content another very important aspect of managing diet in domestic cats (Zoran 2002).

## Conclusion

Diet is extremely important in the lives of felids and can be found in numerous forms dependent on domestication and captivity exposure for various species, as wild felids, captive felids, and domestic cats all exhibit obvious differences in diet. Differences in diet are even more widespread among wild felids due to prey accessibility as a result of individual size and environmental location. Despite the differences associated with diets in felids, species within family Felidae share some dietary characteristics, most notably the

hypercarnivorous, obligate carnivore diet required for survival. Without the consumption of specific nutrients and sustenance provided from animal tissues within the high-protein diet consumed by felids, individuals suffer dire health consequences and are unable to survive and thrive within their respective environments, indicating the large impact diet has on the lives and well-being of felids.

## Synonyms

Cat family; Felidae; Felis; Panthera; Pantherinae; Reproduction; Survival

## Introduction

Felids are made up of two families of cats, the Pantherinae and the Felinae, from the order Carnivora. Extant Pantherinae species, generally referred to as “big cats,” include tigers (*Panthera tigris* spp.), lions (*Panthera leo*), jaguars (*Panthera onca*), leopards (*Panthera pardus*), snow leopards (*Panthera uncia*), and clouded leopards (*Neofelis nebulosa*; *Neofelis diardi*) and diverged from the Felinae between six and ten million years ago (Johnson et al. 2006). Felinae, the “small cats,” is comprised of 36 extant species from 12 genera: cheetahs (*Acinonyx jubatus*); caracals and African golden cats (*Caracal caracal* and *aurata*); bay cats and Asian golden cats (*Catopuma badia* and *temminckii*); Chinese mountain cats, domestic cats, jungle cats, Martelli’s cat, sand cat, black-footed cat, and wildcats (*Felis bieti*, *catus*, *chaus*, *lunensis*, *margarita*, *nigripes*, *silvestris*); jaguarundis (*Herpailurus yagouaroundi*); pantanal cats, colocolos, Geoffroy’s cat, kodkods, southern

tiger cats, Andean mountain cats, pampas cats, ocelots, oncillas, margays (*Leopardus braccatus*, *colocolo*, *geoffroyi*, *guigna*, *guttulus*, *jacobitus*, *pajeros*, *pardalis*, *tigrinus*, *wiedii*); servals (*Leptailurus serval*); Canadian lynx, Eurasian lynx, Iberian lynx, bobcats (*Lynx canadensis*, *lynx*, *pardinus*, *rufus*); Pallas's cats (*Otocolobus manul*); marbled cats (*Pardofelis marmorata*), leopard cats, Sunda leopard cats, flat-headed cats, rusty-spotted cats, fishing cats (*Prionailurus bengalensis* spp., *javanensis*, *planiiceps*, *rubiginosus*, *viverrinus*); and pumas (*Puma concolor*). Of these species, almost all are endangered at some level, with only 12 listed as Least Concern (LC).

The felids emerged in the Oligocene, originating in Eurasia (Johnson et al. 2006). The current eight main lineages emerged, *Panthera* first, 11.3 million years ago (Wei et al. 2011), and then the Felinae: bay cat, caracal, ocelot, lynx, puma, leopard cat, and domestic cat lineages (Johnson et al. 2006).

Felids live on every continent but Antarctica (and are native to all but Antarctica and Australia), although most of the small species are found in closed forest or woodland habitats (Nowell and Jackson 1996) – because of this diversity of environment, they feature differences in life history but also, as expected from a family group, many similarities.

## Reproduction

Felids have four phases of estrus: proestrus (presence of ovarian follicles and increased estrogen), estrus (advanced follicle development, increased estradiol, and behavioral changes such as lordosis, vocalizing, rubbing, and rolling), diestrus (elevated progesterone), and anestrus (low estrogen; Brown 2011). All species are induced ovulators (they ovulate when an external stimulus is present, in this case, mating), but some spontaneous ovulation (which can occur at any time) is present in some species as well, such as clouded leopards, fishing cats, and margays (Brown 2011). Estrus lasts 3–10 days (and can differ not only among species, but between individuals, possibly

due to differences in environment; Brown 2011). Some species reproduce seasonally (domestic cat, tiger, clouded leopard, Pallas's cat, lynx, and snow leopard), while some are not influenced by seasonality (lions, leopards, bobcats, pumas, margays, ocelots, oncillas, jaguars, and fishing cats; Brown 2011).

For solitary species, scent marking is vital to finding mates. There is some evidence that female cheetahs will choose the best mate by interpreting scent marks (Mossotti 2010) in terms of relatedness. Similarly, female domestic cats will leave their home range to find mates if they are related to the cats around them (Liberg 1983). However, mate choice other than for relatedness seems to be absent in females and only present in males (Natoli et al. 2000) – but there is little published work on this subject. Both females and males of most species will mate with more than one cat given the opportunity. In lions, one male will mate with the females in his pride – here, mate choice is related to Dominance, where dominant males have the ability to take over and defend a pride from other males, therefore giving them the opportunity to mate. Male lions that take over prides will practice infanticide in order to spur estrus in females (Nowell and Jackson 1996).

Gestation lasts anywhere from 58 to 108 days (for species that have been recorded; Brown 2006; Gittleman 1986). Litter size varies from 2 to 3.8 kittens/cubs, with birth weights varying from 65 to 1650 g (Gittleman 1986). Weaning age can be as little as 25 days (for leopard cats) and as much as 165 days (in tigers). Kittens/cubs reach puberty and therefore become independent from 4 months (in domestic cats) to 3 years (in lions). Most kittens/cubs are raised by their mothers, with the males playing no part or only a small part in raising young (in lions). As adults, cats range in size from very small to quite large (see ► “Feline Morphology”).

## Survival

Felids range in size from 1.1 kg (rusty-spotted cat) to 306 kg (Amur tiger; Nowell and Jackson 1996), with most species showing sexual dimorphism –

the females are smaller than the males. This vast difference indicates a wide variety of habitats and diet – cats are very well adapted to many ecosystems. As might be expected, felids have a wide variety of home range sizes as well, from 1 (domestic cat) to 2,075 km<sup>2</sup> (African lion; Gittleman and Harvey 1982), although lions more typically seem to range from 26 to 226 km<sup>2</sup> (Viljoen 1993). In addition, semino-madic solitary cheetahs can have much larger territories than smaller coalitions, with the former ranging from 800 to 1500 km<sup>2</sup> (Caro 1994) and the latter from 12 and up to 150 km<sup>2</sup> (Frame 1980; Caro and Collins 1986). In some species, male and female home ranges will overlap, but male territories rarely do. As with many predator species, home range is often dependent on prey availability (MacDonald et al. 2010). All cats scent mark, which allows them to outline their territories and also avoid unnecessary conflicts with other cats.

All felids are obligate carnivores (see ► “[Feline Diet](#)”) and are therefore hunters. However, while cats are predators, the smaller ones are not apex predators and therefore may be preyed upon. In addition, interspecific competition occurs where prey is similar and not plentiful (Macdonald et al. 2010). While the largest of the cats don’t have other animals to fear as adults (cubs may be preyed upon by other big cats, hyenas, jackals, etc.), death is often caused by humans – from habitat destruction, to revenge killings, to trophy hunting, to poaching for fur, teeth, and other body parts believed to promote healing.

The felid social structure can be social or solitary, with fewer species being completely solitary as once thought. Lions, the only fully social species of felid, live in a fission-fusion social group led by one or more males and a group of females and their offspring; young males disperse at puberty (some females also disperse; Packer and Pusey 1987). Males form coalitions, both within the pride and without, allowing them both to hunt and to take over prides. Male cheetahs are known to form coalitions as well (Caro and Collins 1986). Domestic cats will stay in the same area if there is a common, plentiful resource, and females have been known to

alloparent (help raise young that are not their own, although may be related) and form matriarchal groups (Bradshaw 2016; Voith and Borchelt 1986).

## Personality

Personality has not been assessed in all species of felids, but in those that have, there is a remarkable similarity. Generally felids seem to have three dimensions of personality: Neuroticism, Impulsivity, and Dominance, with some traits related to Openness and Agreeableness in some species (Gartner et al. 2014). Differences emerge on the trait level, which explains some behavioral differences, such as sociality in lions. Overall similarities are reflected in similarities in behavior, from hunting to home range establishment, as well as mating, and indicate that personality most likely evolved early in cat species, with later trait development.

Personality has effects on health and in turn is affected by age and sex (see ► “[Personality in Animals](#)”). For example, in cats, well-being is negatively related to Neuroticism – that is, an animal rated higher in Neuroticism will have lower well-being. In addition, while some cat species become more agreeable as they age (Scottish wildcats), some become less so (clouded leopards; Gartner et al. 2014). Impulsivity seems to decrease with age in certain species. Female lions are rated as more Impulsive than males, which makes sense given their society, in which females are the hunters and therefore would rate higher in such traits as active and excitable. Personality also affects strategies of survival. For example, animals that rate higher in Dominance may mate more often, but may also be preyed on more often, whereas animals that rate lower in Dominance may mate less but live longer.

## Special Adaptations

It was long thought that cats could either roar or purr, due to differences in physiology (see

► “[Feline Morphology](#)”). Cats that roar include lions, tigers, jaguars, and leopards. With an increase in research and technology, there is now some debate on this point, with some arguing that the two are not mutually exclusive, others that only lions can truly roar, and some that the original differences are still correct (Kitchener et al. 2010; Peters and Hast 1994; Weissengruber et al. 2002).

Special adaptations for hunting include pelage (see ► “[Feline Morphology](#)”), hearing and eyesight (see ► “[Feline Sensory Systems](#)”), skeletal build (see ► “[Feline Morphology](#)”), paws/claws, whiskers, and teeth, jaws, and tongue (see ► “[Feline Morphology](#)”; Kitchener et al. 2010).

Cats mainly use sight and sound for hunting. As crepuscular hunters that may be active at night and during the day as well, their eyes are adapted for both dark and light (see ► “[Feline Morphology](#)”). They can see six times better than humans can, both in light and dark (Kitchener et al. 2010). While some cats feature especially large ears to aid in hunting animals they can’t necessarily see (e.g., servals), all cats can hear over three times better than humans. This aids in hunting in the smaller cats because rodents communicate on the ultrasonic level (Kitchener et al. 2010). Big cats can hear fainter lower-frequency sounds better than small cats (Huang et al. 2000) – this is likely because their prey is larger, and, in the case of lions, they communicate using low-frequency roaring (Kitchener et al. 2010).

All cats have claws for traction and hunting. Cheetahs are the only cat with nonretractable claws (excepting the dew claw; Hudson et al. 2011). This feature enables them to pursue prey, rather than the typical stalking and ambush style that other felids use, giving them more traction and support (Russell and Bryant 2001). Their soft paw pads allow them to tread quietly while hunting.

Whiskers are one of the most well-known adaptations in cats, who have three sets – above the eyes, on the cheeks, and on snout. Whiskers allow killing bites to appropriately oriented (Kitchener et al. 2010).

Penile spines, present in a number of mammals, are an adaptation of felids as well, but their morphology differs across species – they are thought to stimulate ovulation and are therefore adaptive (Swanson et al. 2003; see ► “[Feline Morphology](#)”).

## Longevity

Felids can live from 10 to 30 years, depending on the species (Kohler et al. 2006). Species in captivity (at zoos or shelters) tend to live longer, due to a lack of predation, a prevalence of food, and attention to physical health.

## Conclusion

Cats are some of the most widespread, adaptable, mammals in the world. While they have a vast amount of features that are similar across the taxon, small differences allow them to adapt to different habitats and prey. However, their adaptability does not protect them from habitat destruction, poaching, and hunting, and most of their numbers are in decline.

## Synonyms

Cat locomotion; Feline gaits

## Definition

Movement used by members of the felid family (e.g., jaguars, cheetahs, lions, domestic cats) to traverse their environment.

Within this chapter, feline is the colloquial term given to members of the family Felidae in the order Carnivora. This includes wild cats, such as the jaguar (*Panthera onca*), the cheetah (*Acinonyx jubatus*), and the lion (*Panthera leo*), and domestic cats (*Felis catus*) (Lamberski 2015). The Felidae family has the largest body size range in the order Carnivora (Lamberski 2015). Felids dwell in diverse habitats, such as forests, bushlands, and deserts, and are found naturally throughout the world, except for polar regions and places such as Madagascar, New Zealand, and Australia, where their presence is a result of anthropogenic introductions (Sicuro and Oliveira 2010).

Felids possess short- to medium-length limbs and utilize digitigrade locomotion. Most felids have retractable claws that are used for climbing trees and capturing prey (Lamberski 2015) and use a “stalk and ambush” approach to hunting (Sicuro and Oliveira 2010). One notable exception is the cheetah, which, unlike most felids, uses its agility and speed to hunt down its prey at incredible speeds (twenty-nine meters per second; Hudson et al. 2012). The cheetah’s claws are not retractable, and are likely used to increase traction while running – thereby creating a functional “cleat.” Felids are carnivorous and their body size and environment impact their diets, which primarily consist of large and small mammals, birds, and occasionally fish (Sicuro and Oliveira 2010).

## Major Locomotor Modes

### Quadrupedal Gaits

Felids use symmetrical walking gaits when moving at slow speeds. Symmetrical gaits occur when footfalls between the forelimb and hindlimb are evenly spaced in time (i.e., walk, pace, or trot) (Granatosky 2018; Miller et al. 1975; Vilensky et al. 1991; Wetzal and Stuart 1976). This is different from asymmetrical gaits, which occur when the forelimb and hindlimb are unevenly spaced in time (e.g., bound, gallop; see below). These symmetrical gaits are further subdivided based on sequence gaits and limb coupling patterns

(Granatosky 2018). A lateral-sequence gait is when each hindlimb footfall is followed by an ipsilateral forelimb footfall. A diagonal-sequence gait is when each hindlimb footfall is followed by a contralateral forelimb footfall. During walking, the forelimbs and hindlimbs of a felid travel in a slight asynchronous couplet. A lateral couplet is when ipsilateral forelimbs and hindlimbs move together, while a diagonal couplet is when contralateral forelimbs and hindlimbs move together. It is very rare for limbs moving together in perfect synchrony (Granatosky 2018). As a whole, felids tend to use either lateral sequence diagonal couplet gaits or lateral sequence lateral couplet gaits (Fig. 1).

Limb-loading for felids (i.e., the external forces acting on the limbs) is quite “standard” for parasagittal mammals. Limb-loading during locomotion can be broken down into mediolateral, horizontal, and vertical components (Granatosky et al. 2018; Fig. 2). The vertical force component is usually of highest magnitude and has been used in numerous studies to understand how animals load their limbs. Felids show a slight forelimb bias for peak vertical magnitude and a characteristic “double-peak” force trace for each limb that is usually associated with limb stiffness.

**Feline Locomotion, Fig. 1** “Hildebrand” plot displaying phase against hindlimb duty factor collected during quadrupedal walking in felines (n = 9 species)

**Feline Locomotion, Fig. 2** Representative force trace collected from a tiger (*Panthera tigris*) during quadrupedal walking. Force is presented as a proportion of the animal's body weight (%bw) over a single forelimb and hindlimb

stance phase. Vertical force is presented in blue, horizontal (fore-aft) in red, and mediolateral in green. Data originally published in Granatosky et al. (2018)

The horizontal force component allows us to explore how animals accelerate and decelerate by examining at the distribution of braking and propulsive forces within a stride. As with most quadrupeds, felids show a distinct braking role for the forelimb and a propulsive functioning hindlimb. Throughout a stride, mediolateral forces are generally low and measure the side-to-side movement of the center of mass (COM) and/or muscular forces applied by the animal to maintain stability. The felids show quite small mediolateral forces (Granatosky et al. 2020).

For many felids, “stealthy” locomotion is essential for capturing prey. Biomechanically, this “stealthy” behavior is achieved by

maintaining a flexed limb posture and flattening the COM trajectory during locomotion. For most striding animals, their COM fluctuates between kinetic energy and potential energy, similarly to an inverted pendulum. During this fluctuation, kinetic energy is temporarily stored as gravitational potential energy, as the COM rises and shifts over the stance leg. It then becomes kinetic energy once again. This exchange between kinetic energy and potential energy reduces the amount of muscle activity needed to accelerate and decelerate the COM. Thus, the costs of locomotion are reduced. However, during “stealthy” locomotion, the flexed limb posture and flattened limb trajectory result in low energy recovery resulting in

increased locomotor costs. The “stealthy” locomotion in felids adds further evidence against the almost axiomatic assumption that energetic economy is the most important target of natural selection, and animals will choose gaits and postures that maximize energetic efficiency (Bishop et al. 2008).

At higher speeds, felids engage in trotting and galloping gaits. During trotting, a felid’s diagonal limbs are in synchrony, and each limb contacts the ground for less than 50% of the locomotor cycle (Vilensky et al. 1991). Trotting allows for the maintenance of stability by decreasing the overall movement of a felid’s COM. As such, the trotting gait has been proposed to conserve energy, and therefore may be the most efficient gait when travelling over long distances (Fig. 3).

Gallop is most often seen when a felid engages in hunting or evasion behaviors. Among the felids, no species is more specialized for speed than the cheetah, which can reach velocities up to ninety-three kilometers per hour. This remarkable speed can be attributed to its use of the rotary gallop, also referred to as a double suspension gallop (Bertram and Gutmann 2009). The double suspension gait is a four-time, asymmetrical gait where the feet fall in a circular sequence around the body, and gets its name from the two aerial phases: a gathered aerial phase, where the back is flexed and the hindfeet pass in front of the forefeet, and an extended aerial phase, where the feet

are stretched away from the body and the back is extended (Bertram and Gutmann 2009; Hudson et al. 2012). Compared to other felids, the cheetahs have hindlimbs that are longer, heavier, and thicker in diameter when scaled to their body mass (Day and Jayne 2007). This has been proposed to allow for increased bone strength and safety to manage the higher magnitude loads during high-speed pursuits (Hudson et al. 2011).

As part of the normal locomotor repertoire, felids must make speed-induced gait transitions. The most common gait transition seen in felids is trotting to galloping. Transition duration and speed are heavily dependent on body size. Moreover, felids use rotary and transverse gallop mechanisms to aid transitions across different speeds (Miller et al. 1975; Vilensky et al. 1991). Rotary transitions highlight changes during hindlimb swing phases, while transverse transitions focus on diagonal limb swing phases (Vilensky et al. 1991). While this gait transition has been described as abrupt in direction and magnitude, some studies have shown that transverse gallops have the potential to occur gradually through smooth forelimb-forelimb and forelimb-hindlimb phase changes (Vilensky et al. 1991). Numerous studies have determined that most transitions occur in the swing phase, are completed within two to three steps, and can occur in normal and decerebrate cats (Miller et al. 1975; Vilensky et al. 1991). During these transitions, there is a defined

**Feline Locomotion, Fig. 3** Illustrative demonstration of (a) the air-righting reflex and (b) feline jumping behavior. (c) The Pneupard is a bio-inspired robotic model used to develop a stronger understanding of feline locomotion,

particularly the cheetah and its fast speeds. Images fall under Creative Commons Attribution-Share Alike 4.0 International

elongation of the feline trunk as well as a strong thrust from the hindlimbs that allow for upward and forward movement (Vilensky et al. 1991).

### Jumping

As a group, the cats are quite well-known for their ability to jump to and from great heights and land safely on all four limbs. Propulsion, or jumping, is a bilateral synchronized movement that involves predominantly hindlimb action (Zajac et al. 1981). However, the starting position of propulsion will vary between different species. Some cats will crouch with both forelimbs touching the ground, while others will crouch with only one forelimb touching the ground and the other flexed. For this reason, forelimbs are not considered to contribute significantly to jumping, but rather are necessary for static stabilization and landing (Zajac et al. 1981).

There are three phases of propulsion during jumping: preparatory, launching, and heel-off (or lift-off). In the preparatory phase, the felid first secures its footing to the ground. It then contracts its forelimb extensor muscles bilaterally to push itself off and throw its body upward. Once the forepaws are off the ground, it keeps its forelimbs in a fully flexed position until it is about to land. During launching, the felid's hindlimb remains in contact with the ground, allowing for the COM to shift toward the hindlimbs from the heels to a point directly over the toes. In heel-off, the hindlimb extensor muscles contract bilaterally, pushing off against the ground, and project the animal's entire body into the air, thus shifting the COM upwards. Once the hindlimbs lose contact with the ground, they also go into flexion. During launching and heel-off, the cat will shift its COM again to allow for further propulsion. This shift in its COM is achieved through extension of the cat's trunk. During launching, the trunk will extend vertically and horizontally, and after heel-off, it will extend vertically. The head and tail do not assist with propulsion. During the jump, the head is maintained at a fixed angle relative to the target and the tail is always pointed upward and never touches the ground (Miller et al. 1975; Zajac et al. 1981; Zomlefer et al. 1977).

During propulsion, the joint angles of the hips, knees, and ankles undergo changes. From the preparatory phase to the launch phase, the hip angle extends from 90° to a maximum of 175°. The knees undergo continuous extension starting from 45° in the preparatory phase until approximately 160° throughout the launch and lift-off phases. The ankle, on the other hand, will start off at 80° and flex to about 60° during launching. The ankle will stop flexing at heel-off and will follow a similar extension trajectory as the knee (Zajac et al. 1981).

When landing, the central pad of the felid's forepaws is the first to contact the ground, providing initial support. The long tendons in its forelimb muscles and the flexibility of its spine allow for the absorption of the rapid and high force impact. This ability of dissipating forces during landing prevents injuries. Two additional factors that are important for landing are height and time. Cats jumping from higher heights have more time to adjust the magnitude of the prelanding limb muscle activity that is appropriate for that height (Wang et al. 2019). Other factors such as hindlimb length and body weight will also affect the height and velocity of the jump. Felids with longer hindlimbs and lower body fat mass relative to lean body mass will achieve higher velocities and greater vertical forces (Zomlefer et al. 1977).

Another key ability that allows cats to land successfully is the air-righting reflex. The air-righting reflex is described as the "ability of cats to turn in the air without pushing against anything and to land upright upon their feet when falling from an inverted or askew position" (Cremieux et al., pg.564). Kittens typically develop this reflex around 33 days. Sensory information is taken from the visual and vestibular systems to perform this reflex. It has been observed that blindfolding a normal adult cat does not prevent the air-righting reflex. Instead, removing their vision affects the accuracy of their landing, likely because they are unaware of the height of the fall (Cremieux et al. 1984). Immediately after mid-air release, the cat will bend its spine first forward, then to one side, then backward, then to the other side, and finally forward again. Rather than "twisting," the bending of its torso and spine

allows the cat to turn over (Manerikar and Anandpara 2015). In addition to bending, cats can project or tuck in their forelimbs and hindlimbs to reorient the pelvis, spine, and torso, and thus still land upright.

### Pacing in Captive Cats

There is a long history of interaction between felids and humans. Apart from the domestication of house cats, humans have also kept larger and wild felids captive in zoos and observation centers. When housing wild cats in smaller and confined areas, wild cats engage in stereotypies and abnormal repetitive behaviors. Stereotypies include licking walls and tongue flicking, while abnormal repetitive behaviors include aggression, self-biting, mutilation, and, most relevant to this chapter, pacing (Breton and Barrot 2014). Pacing behavior is continuous walking back and forth or in a circle, following the same path. Signs of regular pacing include definite paths worn in the ground. Typically, pacing serves no actual function and may be triggered because the felid cannot forage or hunt for their meals (Breton and Barrot 2014; McPhee and Carlstead 2010).

Some studies also demonstrate that these wild cats are under stress, which has negative implications on brain development and reproduction (Breton and Barrot 2014). Prolonged periods of distress can cause high levels of hypothalamic-pituitary-adrenal activity, which can lead to immunosuppression, atrophy of tissue, and maladaptive behaviors (McPhee and Carlstead 2010). For example, a study demonstrated that Siberian tigers (*P. tigris altaica*) at a Bucharest zoo developed gastroenteritis because they could not adapt to their new environment and stress (McPhee and Carlstead 2010). Several other studies on clouded leopards (*Neofelis nebulosa*) and leopard cats (*Felis bengalensis*) found that high levels of glucocorticoids and abnormal behaviors were positively correlated to public displays, proximity of predators, and a lack of different environmental factors (McPhee and Carlstead 2010). Moreover, offspring growing up in captive environments can develop alternative learning behaviors, which can be introduced to the population and reproduced into newer generations of captive felids.

### Bio-inspired Robotics

Bio-inspired robotics has utilized cat models based on both the domestic cat and cheetah. These robotic models not only provide veterinarians and researchers with a deeper understanding of biological parameters of the cat, but also mitigate unethical harm to cats used for research. One such example is the PneuPard model, which has been based on extensive studies performed on real domestic cats, cheetahs, and other quadruped robots (Kajiwara et al. 2018; Nakatsu et al. 2014). Engaging in feline biomimicry, PneuPard models can walk on rough terrain with stability as well as jump and gallop similarly to cheetahs (Rosendo et al. 2013). Moreover, the models can alternatively shift body load and engage in relatively smooth gait transitions (Nakatsu et al. 2014). PneuPard models have informed researchers on how animals perform adaptive locomotion, how muscles contribute to stable gait, and how the spine and limbs influence different gait patterns and transitions (Rosendo et al. 2013). In more recent years, the PneuPard has been used to study how cheetahs can achieve fast speeds.

The PneuPard model has changed rapidly throughout the years, going from a model with two active muscles on each hindlimb to a model with 28 muscles on each hindlimb and 10 muscles on the spine (Rosendo et al. 2012, 2013). Researchers have also begun to focus on the role of monoarticular and biarticular joints in developing computer simulations and robots (Rosendo et al. 2012). It has been found that monoarticular joints generate lateral forces, while biarticular joints transfer forces between the joints, especially during jumping, galloping, and gait transitions (Nakatsu et al. 2014; Rosendo et al. 2013). Researchers have recently developed better robotic landing positions for the PneuPard through different combinations of monoarticular and biarticular joint activation (Rosendo et al. 2012).

### Feline Locomotion in Medicine

Felids have long served as mammalian models for human locomotion after spinal cord injuries (SCIs) (Rossignol et al. 2002; Frigon 2012). Dorsal lesions have been induced in a variety of quadrupeds to examine the impacts on locomotion

(Rossignol et al. 2002). When large lesions were induced into cats, recovery occurred within 10 days, and there were increases in both the cycle and swing phase duration (Kuhtz-Buschbeck et al. 1996; Frigon 2012). Partial lesions of the spine have shown quicker and stronger recovery rates than complete lesions (Kuhtz-Buschbeck et al. 1996). Ventral lesions have not been studied extensively due to harder selectivity constraints, but few studies have demonstrated hindlimb locomotion and weight support recover gradually while lateral stability does not (Frigon 2012). Some studies have highlighted that with extensive treadmill training, felids were able to use their hindlimbs for locomotion after incomplete SCIs because of spinal CPGs (Rossignol et al. 2002).

Both humans and cats have similarly organized spinal cords, including spinal CPGs (Frigon 2012). Spinal CPGs are neuronal networks composed of interneurons that generate movement (Rossignol et al. 2002). These networks interact with sensory systems that stem from the limbs and allow for humans and cats to adapt to their surroundings, such as correcting posture during environmental changes (Rossignol et al. 2002). The spinal CPGs seen in human infants are most similar to feline spinal CPGs because when infants crawl, they exhibit quadrupedal locomotion. However, these human spinal CPGs still retain unique properties that allow for bipedal locomotion (Rossignol et al. 2002; Frigon 2012).

Spinal CPGs are malleable and are important for neuroplasticity, as seen in feline partial SCI studies (Rossignol et al. 2002; Frigon 2012). These CPGs can be generalized between humans and cats, and lesions may help explain motor deficits seen in human patients with SCIs. Studies have implemented intense treadmill training in partial lesioned cats and serve as research designs for human locomotion training and neuroplasticity regeneration in SCI patients.

## Conclusion

Since many cats have been domesticated and wild felids are kept in zoos, researchers have

extensively studied *feline locomotion*. Over time, both domestic and wild cats have adapted to a variety of different environments to stalk and hunt their prey. These quadrupedal animals can locomote with either symmetrical gaits, such as walking and trotting, or asymmetrical gaits, such as galloping. As they move through the environment, conserving their energy is especially important when hunting prey or escaping from predators. However, “stealthy” walking in the felid is costly, and highlights that not all locomotion is optimized for energetic expenditure. In addition, felids also possess impressive jumping abilities and a remarkable air righting reflex. When compared to their wild counterparts, changes in captive feline behavior have been observed and result from the increased stress caused by zoos and closed off environments. When studying feline gait patterns, we gain more insight into their agility, postural balance, and, especially in the case of the cheetah, their speed. Moreover, we can apply this knowledge into the development of bio-inspired robotics and possible clinical treatments for human SCIs.

## Feline Morphology

Brittany D. B. Greene

Independent Researcher, Suffolk, VA, USA

## Synonyms

Cat morphology

## Definition

The shared and unique physical characteristics of felid species contributing to similarities and variations in bodily form.

## Introduction

Forty-one extant felid species exist today, grouped within two subfamilies of the Felidae family:

Pantherinae and Felinae (Kitchener et al. 2017). These species possess a multitude of physical characteristics, each combining into a singular morphology that is considered similar among all cats. This morphology comprised of shared physical characteristics is likely due to a shared genetic lineage among all existing cat species today, dating back 10.8 million years ago to a common ancestor, in the form of a panther-like *Pseudaelurus* species located in Asia (O'Brien and Johnson 2007). The singular morphology that has persisted across time, environment, location, and species within the Felidae family includes similarities in overall body shape, foot and claw structure, facial form, teeth, and presence of coat color patterns, to name a few (Fraser 2012; Sunquist and Sunquist 2002). Many, if not all, shared physical characteristics among felids can be attributed to an overall morphology adapted and evolved for the specialized hypercarnivorous diet that cats thrive upon (Sunquist and Sunquist 2002). Individuals within felid species require a much higher percentage of diet from protein, therefore requiring and showcasing a morphology that reflects an ability to hunt, capture, and kill live prey (Sunquist and Sunquist 2002).

In addition to the aforementioned similarities and an overall singular morphology discussed above, individual felid species also exhibit distinctive characteristics. As sea levels dropped and land bridges appeared millions of years ago, individuals within the *Pseudaelurus* species dispersed and emigrated from Asia to other continents (O'Brien and Johnson 2007). These migrations allowed for the formation of new lineages in which individuals could adapt to new environments and, over time, evolve into today's existing unique felid species with specialized physical characteristics suitable for their respective habitats (O'Brien and Johnson 2007).

## Head

Individuals within family Felidae share defining skull characteristics including a domed shape, a

shortened muzzle, and the presence of a sagittal crest to which strong jaw muscles attach (Sunquist and Sunquist 2002). The presence of the sagittal crest coupled with the shortened muzzle in feline individuals allows for an increased bite force when using canine teeth during hunting (Sunquist and Sunquist 2002). In addition to an increased bite force, felids also have less teeth as a result of the shortened muzzle, with a total of 28 or 30 teeth in the mouth (Sunquist and Sunquist 2002). The teeth are typically comprised of six small incisor teeth located on the top and bottom jaw, four large canine teeth toward the front of the mouth, and molars located at the back of the mouth on the top and bottom jaw referred to as carnassial teeth (Fraser 2012; Sunquist and Sunquist 2002). Each type of tooth is important for different reasons, as incisors are used for holding objects, carnassial teeth are useful when tearing and shredding meat, and canine teeth are relied upon for killing prey (Fraser 2012; Sunquist and Sunquist 2002). The canine teeth are especially important during hunting as prey is rendered inactive and ultimately killed through throat biting and strangulation or cutting of the spinal cord (Fraser 2012; Sunquist and Sunquist 2002). The tongue in felid species is also specialized as a result of the feline diet, as the surface of the tongue is comprised of horny papillae which not only feel rough to the touch but also provide the ability for cleaning flesh off the bone (Fraser 2012). Additionally, felid species possess differing morphology in the structure and positioning of the larynx, pharynx, and hyoid apparatus located below the skull (Hast 1989; Weissengruber et al. 2002). It has been hypothesized that these differences explain why certain felid species (i.e., lion, tiger, jaguar, and leopard) can roar, while all other felids are incapable (Hast 1989; Weissengruber et al. 2002) (Fig. 1).

Felid species also possess vibrissae, most commonly referred to as whiskers. Whiskers are thick sensory hairs deeply rooted beneath the skin that are located in multiple locations on the body including near the eyes, on the chin, and on the legs (Sunquist and Sunquist 2002). However, whiskers are most notably located on both the left and right side of the muzzle on a cat

**Feline Morphology, Fig. 1** The image of a cheetah above showcases the typical dentition observed in felid species: front incisors, large canines, and carnassial teeth at the back of the mouth. (Photo by Brittany D. B. Greene)

(Sunquist and Sunquist 2002). Whiskers are more than just hairs, as they are sensitive to minute movement, touch, and even changes in air currents (Sunquist and Sunquist 2002). As a result, whiskers are invaluable when hunting, especially at night, as the vibrissae move forward when an individual moves in on prey, providing the cat with tactile information regarding the location of the prey relative to itself (Sunquist and Sunquist 2002).

Felid species have large eyes relative to body size and are believed to be able to see the colors green, blue, and red due to the presence of rods and cones within the retina of the eye (Fraser 2012; Sunquist and Sunquist 2002). As individuals in the Felidae family are exclusively hunters, eyesight is very important for prey capture in both light and dark conditions within the environment (Sunquist and Sunquist 2002). Felid species have pupils similar to other species, which can contract and dilate in the presence or absence of light (Sunquist and Sunquist 2002). However, individuals within the Felidae family also possess a reflective tissue in the eye, referred to as the tapetum lucidum, which provides advantageous eyesight that has been hypothesized to be six times more sensitive to light than the human eye (Sunquist and Sunquist 2002). Felid sight is especially well-equipped for navigation, with well-developed peripheral and binocular vision due to high-set, forward-facing eyes (Sunquist and Sunquist 2002). Even so, cat

eyesight does vary depending upon body size, as smaller species of felids, especially the domestic species of cat, *Felis catus*, require and therefore have evolved to have better eyesight for closer objects (Fraser 2012). In contrast, larger felid species, adapted for locating distant prey in larger environments, have evolved to have better long-range sight (Fraser 2012).

## Body

All felids are similar in body shape, with an agile, limber, and muscular body; however, high variation in body size exists both between species and within species (Sunquist and Sunquist 2002). For example, body size ranges drastically in felid species with females of “very large” categorized felid species, such as lions and tigers, weighing approximately 120–130 kg and females of “very small” categorized felid species, such as leopard cats, black-footed cats, and rusty-spotted cats, weighing approximately 1–2.8 kg (Fraser 2012). In addition to body size variation between species, variation in body size and form also exists within species due to factors including geographical location and sexual dimorphism (Pitakarnnop et al. 2017; Sunquist and Sunquist 2002). In fact, Pitakarnnop et al. (2017) noted significant differences in size and shape of bones between male and female domesticated cats.

Similar to variation in body size and form, coat color and pattern are also highly variable between felid species (Sunquist and Sunquist 2002;). Felid coats can contain various markings including rosettes, blotches, spots, and stripes or appear solidly colored (Sunquist and Sunquist 2002). These various markings on felid coats are believed to have evolved from a primitive “fleck,” or spot, pattern in ancestral felid species (Werdelin and Olsson 1997). The high variability observed in coat pattern and color is likely due to the behavior of each species within its environment as well as the need for each species to camouflage into its respective environment (Allen et al. 2011). Allen et al. (2011) determined that species with more “complex” flank markings were more likely to be arboreal and

found in closed environments, such as forested habitats. In addition, Allen et al. (2011) noted “especially irregular” flank markings were also most prominent on nocturnal hunters, arboreal hunters, and tropical-forest dwelling cats.

## Appendages

Felid species have five toes on their forepaws and four toes on their hind paws and present themselves as limber creatures due to their muscular forelimbs and hindlimbs as well as possessing the pedal quality referred to as digitigrade (Fraser 2012; Sunquist and Sunquist 2002). All felid species are digitigrade, meaning all individuals within felid species walk on, and distribute their weight onto, their highly sensitive toe and paw pads (Fraser 2012; Sunquist & Sunquist). This locomotive characteristic allows for weight distribution to the balls of the feet, enabling the signature agile movement observed in cat species (Sunquist and Sunquist 2002).

All felid species possess sharp, curved claws that are typically protected by sheaths within the toes of each paw (Fraser 2012). These claws are retractable when an individual is at rest due to a flexible ligament, though can be released quickly using a specialized muscle referred to as the flexor profundus perforans (Fraser 2012; Sunquist and Sunquist 2002). Though all species within family Felidae possess the same morphology allowing for the ability to retract their claws, certain species including the cheetah, the serval, and the flat-headed cat have claws that remain visible and appear nonretractable, even at rest (Sunquist and Sunquist 2002). This is due to the presence of claws that extend further than the fur on the paws for all species previously mentioned, though cheetahs additionally lack the previously mentioned sheaths protecting the claws (Sunquist and Sunquist 2002). The claws in felid species are an important morphological trait, as they provide individuals with the ability to scratch, climb, and, most importantly, hold prey (Fraser 2012; Sunquist and Sunquist 2002). In fact, within the order Carnivora, felids are the only carnivores known to use the claws on their forepaws to

**Feline Morphology, Fig. 2** The above image details the paws of a cheetah, including the paw pads all digitigrade felid individuals walk upon, as well as the uniquely cheetah characteristic of seemingly unretractable claws

restrict prey movement prior to administering a lethal bite at the throat (Sunquist and Sunquist 2002) (Fig. 2).

Tails are a prominent feature typically observed in felids as well and are a highly flexible anatomical trait that can aid individuals in balance and changing direction rapidly (Fraser 2012; Sunquist and Sunquist 2002). The majority of felids possess long tails ranging from 1/3 to 1/2 of the combined length of the head and body (Sunquist and Sunquist 2002). Even so, exceptions exist to this rule, as species such as the margay, clouded leopard, and marbled cat have unusually long tails, and bobcat and lynx species have very short tails (Sunquist and Sunquist 2002).

## Conclusion

Felid species possess multiple physical characteristics and traits that are shared among individuals within family Felidae, thus producing an overall recognizable singular morphology within the family. Though similar in overall form, felid species vary greatly in size and physical characteristics that developed over time due to survival requirements put forth in each species' respective environment. This similar morphology interspersed with adaptive traits and physical characteristics specific to each species has allowed for the development of a simultaneously uniformly

congruous and richly diverse grouping of species within family Felidae.

## Feline Navigation

Brittany D. B. Greene  
Independent Researcher, Suffolk, VA, USA

### Synonyms

[Cat navigation](#); [Feline dispersal](#)

### Definition

The process in which individuals within family Felidae identify their location relative to, and move throughout, the surrounding environment.

### Introduction

Navigation in nonhuman animal species, including the cat, has long been, and in some ways still remains, a mystery to scientists (Belluck 2013; Kluger 2015). However, strides have been made recently to further understand nonhuman animal navigation. Nonhuman animal species, such as sea birds and dung beetles, are believed to navigate using the sun and stars, dogs are believed to rely upon scent for navigation, and baby sea turtles are believed to use magnetism when migrating and navigating after hatching (Kluger 2015). Felids are believed to navigate similarly to baby

sea turtles, relying upon Earth's magnetic fields to navigate within their environments, possibly due to the presence of iron within their ears (Kluger 2015). This ability to navigate using Earth's magnetic field may explain the uncanny ability of felid species to move around within their environments. This renowned ability has been referred to as a “homing ability” or “homing powers” in felids and has been noted throughout history, including multiple examples of various house cats traveling between 200 and 1000 miles to return home after traveling for months (Belluck 2013; Herrick 1922). This seemingly effortless “homing ability” in felids can be attributed to physical characteristics and related to movement capabilities. Physically, felids possess a morphology ideal for navigating within their respective environments. Additionally, felids must also be capable of dispersing and establishing territories or home ranges within their respective environments that they can move within and return to using their “homing ability.”

### Felid Morphology Aiding in Navigation

In addition to iron within their ears that may contribute to their impressive navigation skills, felid species also possess a multitude of physical characteristics and sensing systems that aid in navigation within their respective environments. For example, within familiar locations, cats are hypothesized to memorize locations using their olfactory and visual senses (Belluck 2013). This is but one reason that sight is an important sense for a feline when navigating within the environment. In addition, several felid species are nocturnal or exhibit nocturnal behaviors (Fraser 2012). Therefore, they require, and possess, morphological traits capable of navigating in low light conditions. Felid eyesight is highly responsive in varying light conditions, as felid eyes are dominated by “light-sensitive” rod cells within the retina that aid in eyesight in darker conditions (Sunquist and Sunquist 2002). In fact, felids are believed to have much better eyesight than humans in low light conditions (Fraser 2012). Felid pupils are capable of contracting and dilating in the presence or absence of light, thereby

controlling the amount of light that enters the eye (Sunquist and Sunquist 2002). Felids also possess a reflective tissue in the eye, referred to as the tapetum lucidum (Sunquist and Sunquist 2002). This “mirror-like” structure, located behind the retina, aids in dispersing and reflecting light, providing cats with eyesight that has been hypothesized to be six times more sensitive to light than the human eye (Fraser 2012; Sunquist and Sunquist 2002). These adaptations allow for the ability to hunt in varying light conditions ranging from bright daylight during the day to obscuring darkness at night (Sunquist and Sunquist 2002).

Just as eyesight is important in navigation, olfactory sensing is also helpful in navigating the socially constructed territories possessed by individual felids within their respective environments. Olfactory sensing is used a great deal in the social lives of felids, as scent is used abundantly for communicating intraspecifically and interspecifically within the environment of felids (Sunquist and Sunquist 2002). Scent-marking is commonly conducted where felid ranges overlap, and female individuals have been observed increasing urine-spraying prior to fertile periods with the hopes of attracting a mate (Sunquist and Sunquist 2002). Scents and odors produced by felids are believed to indicate such information as sex, status, breeding condition, temporal details, and identity (Sunquist and Sunquist 2002).

Auditory sensing can aid in navigation for hunting as well. Felids, especially the serval species (*Leptailurus serval*), utilize the outer ears, referred to as the pinnae, to both amplify and locate sound (Sunquist and Sunquist 2002). Felids can also hear ultrasonic sounds, though they do not communicate through ultrasonic sound (Sunquist and Sunquist 2002). It has been hypothesized that the ability to hear at ultrasonic levels in felids is likely specialized for hunting, especially in smaller felid species that hunt rodent prey that communicate using sounds within the range of 20–50 kHz (Sunquist and Sunquist 2002).

Tactile sensing is also beneficial for navigation. Felid species possess vibrissae, most commonly referred to as whiskers, to aid in tactile sensing. Whiskers are thick sensory hairs deeply rooted beneath the skin that are located in multiple

locations on the body including near the eyes, on the chin, and on the legs (Sunquist and Sunquist 2002). However, whiskers are most notably located on both the left and right side of the muzzle on a cat (Sunquist and Sunquist 2002). Whiskers are more than just hairs, as they are connected to nerve endings, thereby making them quite sensitive to minute movement, touch, and even changes in air currents (Sunquist and Sunquist 2002). The tactile sensing from whiskers helps cats better understand their location and proximity to objects within the environment (Hanlon 2016). As a result, whiskers are invaluable when hunting, especially at night, as the vibrissae move forward when an individual moves in on prey, providing the cat with tactile information regarding the location of the prey relative to itself (Sunquist and Sunquist 2002).

## Felid Dispersal and Navigation Within the Environment

Location within the environment can also have a huge impact on feline navigation. Most felids undergo a process known as dispersal, in which recently matured individuals socially disengage from family members, leave their mothers' territories, and embark on a journey in search of their own respective territories (Fraser 2012). This period of dispersal is markedly asocial, with individuals in various felid species able to potentially disperse over 100 km and males typically traveling farther than females in search of a territory (Fraser 2012). Though this behavior is common in wild felids, domestic cats have not been observed to exhibit obvious dispersal impulses, likely due to the restrictive nature of a living in a home with a continuous food source (Fraser 2012).

After eventual establishment of a territory or home range, wild felids have been known to travel back to those territories or home ranges when removed and translocated, likely using the “homing ability” previously discussed. For example, following translocation to locations nearly 310 miles from their home ranges, two separate male pumas returned to their respective home ranges. One male traveled a total of 288 miles (465 km) back to his home range over a period

of 469 days, while the other male traveled a total of 305 miles (490 km) over a period of 166 days (Sunquist and Sunquist 2014). In addition to traveling back to a home range or territory, navigation can impact the behavior of wild felids within their territories as well. Within their home ranges, wild felids have been observed to frequent man-made structures, including roads and trails, for movement throughout the environment. Sunquist (1981) noted that tigers (*Panthera tigris*) not only frequented roads and trails but that they were considered an important source for movement within the ranges of the tigers. Sunquist (1981) also noted that the movements of the tigers along the roads and trails were highly directional and likely used for facilitating quick navigation within the tigers' home ranges. Similarly, though less frequent, leopards (*Panthera pardus*) were also observed using roadways for travel within the same national park in Nepal (Sunquist 1981).

Unfortunately, increased frequency of felids using human-made structures also puts those individuals at increased risk of entering into potential situations of conflict with humans. Inskip and Zimmerman (2009), after reviewing 349 literature sources regarding human-wildlife conflict involving 37 felid species, noted that habitat availability, impacted by the need to navigate extensive home ranges overlapping with human-dominated areas, was one of six main determinants of conflict between humans and felids. However, studies, such as that conducted by Haidir et al. (2020) examining Sunda clouded leopards (*Neofelis diardi diardi*), Asiatic golden cats (*Catopuma temminckii*), and marbled cats (*Pardofelis marmorata*), have been conducted to research corridor land use in felid species, with the hopes of identifying and protecting safe passages for navigating felid individuals in an uncertain future.

## Conclusion

Navigation capability is an important trait for wild felid individuals and domestic individuals alike. Individuals within family Felidae can be exceptionally adept at navigating within their environments as a result of morphological traits. Felids possess an extraordinary homing ability, likely as

a result of morphology adapted for successfully moving around within the environment. Location can be highly impactful on navigation as well, as felid individuals entering adulthood disperse, establish their own territories or home ranges, and move around within those areas. Human-made structures, including roads and trails, have been observed to be utilized, sometimes frequently, by felid species as a means of navigating within their home ranges; however, though these human-made structures are important for felid navigation, increased interaction of wild felids and humans has contributed to conflict in areas where human and carnivore habitat overlap. Nonetheless, there is hope for the future, as researchers work to identify, and advocate for, safe navigable routes for felids within their home ranges.

providing for social interspecific and intraspecific interaction within the surrounding environment.

## Introduction

Forty-one extant felid species exist today, grouped within two subfamilies of the Felidae family: *Pantherinae* and *Felinae* (Kitchener et al. 2017). These species possess a multitude of physical characteristics, each combining into a singular morphology that is considered similar among all cats. Many, if not all, shared physical characteristics among felids can be attributed to an overall morphology adapted and evolved for the specialized hypercarnivorous diet which cats thrive upon (Sunquist and Sunquist 2002). Individuals within felid species require a much higher percentage of diet from protein, therefore requiring and showcasing a morphology with sensory systems equipped for hunting live prey (Sunquist and Sunquist 2002). Such sensory systems are also important for individual feline well-being (Fraser 2012). These sensory systems are comprised of visual, olfactory, gustatory, auditory, vestibular, and tactile sensing.

## Visual Sensing

The visual sensory ability is the primary sense used by individuals within family Felidae when hunting prey (Sunquist and Sunquist 2002). Felids possess advantageous evolutionary adaptations in eye morphology that allows superior eyesight and the capacity to successfully hunt and catch prey. Felid eyesight is highly responsive in varying light conditions, as felid eyes are dominated by “light-sensitive” rod cells within the retina that aid in eyesight in darker conditions (Sunquist and Sunquist 2002). In fact, felids are believed to have much better eyesight than humans in low light conditions (Fraser 2012). Felid pupils are capable of contracting and dilating in the presence or absence of light, thereby controlling the amount of light that enters the eye (Sunquist and Sunquist 2002). Felids also possess a reflective tissue in the eye, referred to as the tapetum lucidum (Sunquist and Sunquist 2002). This

## Definition

Developed visual, olfactory, gustatory, auditory, vestibular, and tactile senses in felid species resulting from evolved morphological traits ideal for supporting the ability to hunt as well as

“mirror-like” structure, located behind the retina, aids in dispersing and reflecting light, providing cats with eyesight that has been hypothesized to be six times more sensitive to light than the human eye (Fraser 2012; Sunquist and Sunquist 2002). These adaptations allow for the ability to hunt in varying light conditions ranging from bright daylight during the day to obscuring darkness at night (Sunquist and Sunquist 2002). In addition to a sensitivity to visible light, felids, among other mammals, are also believed to be sensitive to UV light (Douglas and Jeffery 2014). Eye lenses of domestic housecats (*Felis catus*) were observed to let in significant amounts of UVA, between 315 nm and 400 nm, proposing the argument that felids may also be able to see within the UV spectrum (Douglas and Jeffery 2014).

In addition to a sensitivity to light, felid eyes also are believed to be able to detect such colors as green, blue, and red in bright light conditions (Sunquist and Sunquist 2002). Even so, it is believed that felids are unable to detect fully saturated colors or as many colors as humans due to an insufficiency in color-detecting cones within the retina (Sunquist and Sunquist 2002). Felids, however, have enhanced binocular vision that is believed to be superior to all other species in order Carnivora due to high-set, forward-facing eyes (Sunquist and Sunquist 2002). Felids can focus eyesight, and swiftly adjust that focus, exceptionally well due to the location of the lens further back in the eye (Fraser 2012). Interestingly, even with superior binocular vision, cat eyesight does vary depending on body size (Fraser 2012). Smaller species of felids, especially domestic housecats, require and therefore have evolved to have larger eyes coupled with better eyesight for closer objects (Fraser 2012). In contrast, larger felid species, adapted for locating distant prey in larger environments, have evolved to have smaller eyes coupled with better long-range sight (Fraser 2012). All felid species also have enhanced peripheral vision, resulting in individuals rarely focusing eyesight when at rest (Sunquist and Sunquist 2002).

## Olfactory and Gustatory Sensing

Olfactory (smell) and gustatory (taste) sensing function similarly, with chemical stimuli interacting with receptors, such as taste buds, located on a mucous membrane, such as the tongue or nasal membrane (Fraser 2012). Both senses are considered “chemical senses,” as they are reliant upon and responsive to chemical stimuli, in contrast to all other senses responsive to light, vibration, and pressure (Fraser 2012). In fact, olfactory receptor cells within the nose can integrate smell and taste together when sensing a stimulus (Fraser 2012).

Olfactory and gustatory sensing impact food preference, as felids partially rely upon both taste and smell for determining if a food is considered ingestible (Fraser 2012). Even so, multiple studies have found nutritional profile to be a large determining factor, potentially even over taste, when choosing diet (Watson 2011). Nonetheless, taste does have an impact on food preference to some degree. Not unlike numerous other mammal species within Carnivora, the taste buds of a felid, located on the frontal portion of the tongue, show no preference for carbohydrate sweeteners due to genetics resulting in a lack of sweet taste receptors (Beauchamp et al. 1977; Fraser 2012; Jiang et al. 2012; Li et al. 2006). This lack of sweet taste receptors is hypothesized as one of the reasons felids are strictly carnivorous (Li et al. 2006). Though lacking in sweet taste receptors, housecats have been found to prefer ingesting some amino acids over others, especially avoiding those with mildly bitter to strongly bitter flavors (White and Boudreau 1975). Even with housecats believed to potentially discern bitter taste differently than humans do, this is likely as a result of the bitter taste receptors housecats possess (Lei et al. 2015; Sandau et al. 2015).

Gustatory sensations are also important in intraspecific interactions, such as licking other feline individuals (Fraser 2012). It has been hypothesized that taste sensing is even useful for a mother cat after giving birth (Fraser 2012). The gustatory sense is believed to be utilized while

cleaning neonatal kittens, aiding in a mother cat developing kin recognition (Fraser 2012).

Though less understood, the significance of olfactory sensing in the lives of felids is still acknowledged. Olfactory sensing is conducted through the nasal membranes and olfactory bulb, with odor information believed to be ascertained in the olfactory area of the cerebral cortex of the brain (Fraser 2012). Though not as sensitive as canines, felids are believed to have a keen sense of smell, with mother cats able to differentiate between the scent of their own young and “alien offspring” (Bánszegi et al. 2017; Sunquist and Sunquist 2002).

Olfactory sensing is used a great deal in the social lives of felids, as scent is used abundantly for communicating intraspecifically and interspecifically within the environment of felids (Sunquist and Sunquist 2002). Scent-marking is commonly conducted where felid ranges overlap, and female individuals have been observed increasing urine-spraying prior to fertile periods with the hopes of attracting a mate (Sunquist and Sunquist 2002). Scents and odors produced by felids are believed to indicate such information as sex, status, breeding condition, temporal details, and identity (Sunquist and Sunquist 2002). In fact, odor from anal-sac secretions in housecats is believed to provide conspecifics with an individual’s identity information, versus species level or even sexual information (Miyazaki et al. 2018).

Felids also possess a vomeronasal organ, also referred to as the Jacobson’s organ, which is comprised of two small tubes located in the nasal passages and specialized for aerosolized scent uptake of pheromones (Fraser 2012; Verberne 1976). When a pheromone is detected, a response referred to as flehmen is typically observed, in which an individual’s mouth opens, upper lip raises, and tongue-flicking occurs (Pageat and Gaultier 2003). Flehmen, though a strange observation to witness firsthand, aids in the uptake of pheromones into the vomeronasal organ (Pageat and Gaultier 2003). The vomeronasal organ is believed to be primarily utilized for detection of

sexual pheromones and potential breeding prospects (Fraser 2012). Felids possess six significant areas for secreting pheromones (Pageat and Gaultier 2003). Pheromones are produced from pheromone-secreting glands located in the facial area, the pedal complex (all four legs), the perianal complex, the genital complex, and the mammary complex and can also be found in feces and urine (Pageat and Gaultier 2003).

## Auditory and Vestibular Sensing

The auditory sense, or ability to hear, is highly developed in felids when compared with humans and even canines (Fraser 2012; Sunquist and Sunquist 2002). Felids, especially the serval species (*Leptailurus serval*), utilize the outer ears, referred to as the pinnae, to both amplify and locate sound (Sunquist and Sunquist 2002). Additionally, felids have been categorized as one of the mammals most able to perceive sounds made at middle frequencies within the range of 1–20 kHz (Bradshaw et al. 2012). Felids can also hear ultrasonic sounds, in the range of 60–80 kHz, compared with humans, which are only capable of hearing sounds up to 15–20 kHz (Sunquist and Sunquist 2002). As felids do not communicate through ultrasonic sound, the ability to hear at ultrasonic levels is likely specialized for hunting, especially in smaller felid species that hunt rodent prey that communicate using sounds within the range of 20–50 kHz (Sunquist and Sunquist 2002). Though it can aid in hunting prey, ultrasonic hearing can also be detrimental to the well-being of cats as loud noises can be harmful to hearing in felids (Fraser 2012).

Balance, brought about by the inner workings of the vestibular system within the inner ear, is also an important sense in felids (Bradshaw et al. 2012). This sense is especially developed in felids as a result of specialized inner ear morphology (Bradshaw et al. 2012). The heightened sense of balance as a result of the vestibular system aids felids in successful hunting, carefully navigating narrow walkways, landing right side up following

a fall, and staving off motion sickness (Bradshaw et al. 2012; Fraser 2012).

## Tactile Sensing

Tactile sensing, or touch, is also important in individual well-being and function for felids (Fraser 2012). Felids are believed to possess 15 different types of receptors related to tactile sensing (Bradshaw et al. 2012). These receptors are partitioned into three groupings including mechanoreceptors responsive to touch and pressure, thermoreceptors responsive to temperature, and nociceptors believed to be responsive to pain (Bradshaw et al. 2012). The mechanoreceptors can be further partitioned into two groupings based on responsiveness to the presence of maintained versus inconsistent touch or pressure (Bradshaw et al. 2012). Felid species contain varying amounts of mechanoreceptors all over the body, with abundant mechanoreceptors found in the nose and front paw pads (Bradshaw et al. 2012). The abundance of mechanoreceptors in the front paw pads aids in hunting, while the sensitive nose is believed to be used for examining temperature in newborn kittens (Bradshaw et al. 2012; Fraser 2012).

Felid species also possess vibrissae, most commonly referred to as whiskers, to aid in tactile sensing. Whiskers are thick sensory hairs deeply rooted beneath the skin that are located in multiple locations on the body including near the eyes, on the chin, and on the legs (Sunquist and Sunquist 2002). However, whiskers are most notably located on both the left and right side of the muzzle on a cat (Sunquist and Sunquist 2002). Whiskers are more than just hairs, as they are connected to nerve endings, thereby making them quite sensitive to minute movement, touch, and even changes in air currents (Sunquist and Sunquist 2002). As a result, whiskers are invaluable when hunting, especially at night, as the vibrissae move forward when an individual moves in on prey, providing the cat with tactile information regarding the location of the prey relative to itself (Sunquist and Sunquist 2002).

In addition to moving forward while hunting, whiskers also notably move forward when an individual is aggressive or backward when an individual is fearful (Fraser 2012).

## Conclusion

Species within the Felidae family have evolved visual, olfactory, gustatory, auditory, vestibular, and tactile senses ideal for supporting the ability to hunt as well as provide for social inter-specific and intraspecific interaction within the surrounding environment. While all the aforementioned senses in felids function at a high-level individually, it is the integration of these senses as part of a singular morphology that has allowed felids to navigate throughout their respective environments, thriving as uniquely successful predators.

## Female Choice

Rachel M. Petersen  
New York University, New York, NY, USA

### Synonyms

[Intersexual selection](#); [Mate choice](#)

### Definition

Process by which females can bias paternity of their offspring to certain categories of males.

### Introduction

Sexual selection acts on variation in traits that affect reproductive success. Sexual selection can occur via competition between members of the same sex for reproductive opportunities with members of the opposite sex (intrasexual selection) or through mate choice for attractive members of the opposite sex (intersexual selection). Whereas intrasexual selection has traditionally been thought to act more strongly on males via male-male competition leading to male weaponry and body size dimorphism (direct competition) and large testis volume (indirect competition), intersexual selection has been thought to act more strongly on females choosing males due to differences in life history and parental investment between the sexes. Female choice is a form of

intersexual selection by which females can increase their reproductive success by biasing paternity of their offspring toward certain males (Andersson 1994).

Here, different types of female mate choice in relation to male attributes are described with examples. The benefits that these choices might confer to females are also discussed. This description is limited to examples between members of the same species and does not cover mechanisms of mate choice that might act to create and maintain isolation between species. This entry is organized into four non-mutually exclusive types of female choice in relation to the timing of mating and type of female discrimination: direct precopulatory choice, indirect precopulatory choice, direct postcopulatory choice, and indirect postcopulatory choice. Precopulatory choice happens before the act of mating, and postcopulatory choice occurs during or after the act of mating. Direct female choice occurs via active discrimination between males based on male attributes. Indirect female choice is a process whereby females elicit male-male competition, as an indirect mechanism for discriminating between males.

Although the terminology associated with female choice can sometimes imply reasoning and higher-level cognition, female choice does not refer to any type of conscious decision-making regarding preference. Whereas females of certain species may have the capacity for top-down modulation of reproductive behavior, most examples of female choice are thought to be the product of affective state and arousal in response to different males and their exhibited signals.

### Direct Precopulatory Choice

Direct precopulatory choice occurs when females influence male mating success by behaviorally discriminating between particular categories of males. This type of female choice received the most attention from Darwin and other early evolutionary biologists, due to the vibrant ornamentation and courtship displays that may evolve in males in response to such choice. Direct

precopulatory female choice is best described in aquatic and avian species, where females tend not to live in large aggregations and can escape male coercive tactics more easily across three dimensions. There is relatively less evidence for direct precopulatory female choice in terrestrial mammals, where females commonly live in monopolizable groups to avoid predation and in which marked sexual dimorphism has commonly evolved to facilitate male coercion (Clutton-Brock and McAuliffe 2009).

Selection favors females that can perceive informative cues to assess male attractiveness and alter their behavior accordingly. Females perceive mate quality through multiple communicatory modalities, including visual, auditory, and olfactory channels. Color vision is hypothesized to have evolved in a feeding context; however, females may exploit this adaptation to assess cues of male quality, such as plumage or skin color. Signal symmetry is another trait hypothesized to be assessed by females during mate choice due to its reflection of an individual's ability to cope with environmental stressors during development. Male vocalizations can be helpful in locating a male, but females have also evolved the capacity to gain information about male quality, such as body size, from these vocalizations. The assessment of olfactory cues may be especially important for females to ensure the genetic quality of their offspring. The sensory systems most affected by selection on female perception of male attractiveness will depend on the ecology of the species, including issues related to signal bandwidth and noise structures in the environment.

Female perception of male genetic characteristics and subsequent mating preferences can favor males possessing "good genes," or males with genetic compatibility to the female. Genetic compatibility refers to the interaction between the male and female genome, whereby females may prefer males possessing alleles that complement their own, as opposed to males possessing particular genotypes, or overall diversity. Genetic compatibility is implicated in inbreeding avoidance, which decreases the probability of disadvantageous recessive alleles being inherited and expressed and increases overall heterozygosity.

Heterozygosity throughout the genome is known to increase survival in numerous species through enhanced disease resistance, growth rate, and developmental stability (Allendorf and Leary 1986; Brown 1997). Female discrimination between kin and non-kin may occur based on familiarity during development, or through multiple hypothesized mechanisms of phenotypic matching, including via olfactory signals.

One area of the genome that may be especially important in female choice is the major histocompatibility complex (MHC), a highly polymorphic area of the genome that is involved with pathogen identification and immune response regulation. The "good genes" hypothesis predicts that females will prefer males with specific or diverse MHC types, causing mate choice between females to converge on certain types of males. This is observed in the great snipe (*Gallinago media*), a lekking bird species, where males with certain MHC alleles experienced higher mating success, regardless of female MHC type (Ekblom et al. 2004). Conversely, mate choice for genetic complementarity appears to be important in many other species. In sticklebacks (*Gasterosteus aculeatus*), females mate non-randomly in a manner that optimizes the number of MHC alleles that her offspring will inherit, and, in sand lizards (*Lacerta agilis*), females prefer the odors of males more distantly related at the MHC class I loci (Aeschlimann et al. 2003; Olsson et al. 2003). There is growing evidence that females perceive genetic characteristics via olfactory signals, due to the MHC's influence on the gut microbiome and associated volatile molecules related to body odor (Ziegler et al. 2005).

Once preferred mating partners are identified, females can facilitate mating with proceptive behaviors. Proceptive behaviors refer to active initiation and maintenance of sexual encounters and are distinct from receptive behaviors, which indicate only a willingness to copulate. Proceptive behaviors can include bodily postures, facial expressions, and locomotor patterns aimed to encourage male sexual arousal. Female-initiated reproductive behaviors, even in the most sexually dimorphic species with the largest scope for male sexual coercion, can have fitness consequences.

For example, female mandrills maintain proximity and engage in sexual presentations to males with the most brightly colored faces, which translates into higher mating success for brightly colored males, independent of dominance rank (Setchell 2005).

Female perception of male attractiveness and directed proceptivity has numerous documented effects on male morphology, physiology, and behavior. Male ornamentation and courtship displays are secondary sexual characteristics hypothesized to have evolved through female mate choice. The “good genes” hypothesis predicts that exaggerated secondary sexual traits convey honest information about male quality (Andersson 1986). Many male secondary sexual characteristics develop in correlation with increased production of androgens, such as testosterone, leading to sexual maturation. Androgens are associated with suppression of the immune system, and secondary sexual traits are hypothesized to develop in a trade-off with a male’s immunological status, so helping to maintain signal honesty (Hamilton and Zuk 1982). Conversely, the “runaway selection” hypothesis posits that exaggerated male secondary sexual characteristics do not communicate aspects of male quality and instead may simply be the result of the coevolution of male phenotype and a female preference for male traits based on female preexisting sensory biases (Fisher 1915). The challenging nature of explicitly demonstrating that a male trait does not communicate any aspect of male quality leaves the process of runaway selection difficult to substantiate.

Male qualities that are influenced by the local environment and provide direct fitness benefits, such as fertilization ability and paternal investment ability, can also be communicated via male secondary sexual characteristics and used to inform female mating decisions. Sperm depletion after successive matings is well known in many species to influence female mate choice. For example, female lemon tetra (*Hyphessobrycon pulchripinnis*) preferentially mate with males that have not spawned recently and avoid males with reduced sperm supply (Nakatsuru and Kramer 1982). Sperm supply may be communicated through physical or behavioral changes,

such as the extent of courtship. Courtship success in *Drosophila* is reduced after sperm depletion, and there is a correlation between male courtship display rate and sperm supply in smooth newts (*Triturus vulgaris*) and checkered white butterflies (*Pieris protodice*) (Halliday 1977; Markow et al. 1978; Rutowski 1979).

In species with paternal care, a male’s ability to invest in offspring can also be an important factor influencing female mate choice. Male nutritional state and parenting experience are important aspects of male quality impacting male parental ability. In moorhens (*Gallinula chloropus*), females compete for access to fat males with large energy reserves which allow them to incubate eggs for longer (Petrie 1983). Red-winged blackbird females (*Agelaius phoeniceus*) prefer experienced fathers who tend to feed their offspring more and are able to identify them based on their larger song repertoires and longer courtship displays (Yasukawa 1981). Courtship is also an honest indicator of subsequent paternal investment in the bicolor damselfish (*Stegastes partitus*). Males with larger body fat reserves perform longer courtships, guard eggs for longer periods of time, and are less prone to cannibalizing eggs (Knapp and Kovach 1991).

In some species of birds and insects, males provide females with nutrition during courtship. The size of nuptial gifts can impact the probability of copulation and be indicative of future paternal investment, as in the common tern (*Sterna hirundo*), where the rate at which a male feeds a female during courtship is correlated with that male’s later rate of feeding to the resultant offspring (Nisbet 1973). These types of gifts can benefit the female in two ways. In species where finding prey is dangerous, nuptial gifts increase a female’s survival probability by reducing her hunting time. Females also gain increased resources to invest in increased fecundity. In species exhibiting individual discrimination, exchanging food or other types of support (e.g., protection from predators, grooming) for mating opportunities may happen on longer timescales, although evidence for this is limited (Gomes and Boesch 2009).

## Indirect Precopulatory Choice

Indirect precopulatory choice occurs when male contest competition and female choice work in combination. Under this scenario, females bypass the need to actively discriminate between males based on attractiveness and instead incite male-male competition, with mating access then granted to the male that wins. Multiple species achieve this by signaling fertility in different communication modalities. Swelling of the perineal skin in multiple species of primates around the fertile phase of the cycle is hypothesized to have evolved because it stimulates competition among males (Nunn 1999). Acoustic signals of fertility work in the same manner and have been documented in the estrus calls of a number of different mammalian species and groups, such as African elephants, Old World monkeys, and bovids (Gouzoules et al. 1998; Poole 1989; Pradhan et al. 2006; Yeon et al. 2006). Delivering a call during times of peak fertility advertises the female's sexual receptivity and encourages dominant males to supplant subordinate males and engage in mating and subsequent mate guarding.

Evasive behaviors are another method by which a female can ensure that she mates only with males of a certain type without needing to discriminate between them. Ducks, barn swallows, and tree squirrels all engage in indirect female choice by running away from potential mates (Koprowski 1993; McKinney et al. 1983; Møller and Gregersen 1994). The first male that is able to catch the female has the opportunity to mate with her, which may limit mating partners to those males in top physical condition.

Female aggregation, sometimes at predetermined locations, has also been suggested to act as a means of indirect female choice. Grouping of receptive females facilitates herding by males and promotes competition between males for exclusive access. In some Caribbean fish, females return to the same location year after year to spawn, and males compete for access to females in these areas (Domeier and Colin 1997). Although these areas do have advantages, such as abundant food or protection from predators, the locations are chosen relatively arbitrarily

(i.e., there are many locations with similar food and predator densities) and are learned from previous generations. Many species of insects engage in a similar kind of behavior called "hill-topping." Males compete among each other for access to the highest elevated areas, and females mate with those males possessing those territories, thereby mating with males of the highest competitive ability without actively discriminating between male qualities (Alcock 1987).

Indirect female choice can also be related to resource holding in males. For example, female Grevy's zebras (*Equus grevyi*) late in gestation will restrict their ranges to areas with watering holes to sustain lactation (Rubenstein 1986). Males holding these areas in their territory have exclusive mating access to lactating females during their post-estrus cycle. As such, females are more likely to mate with males that are able to defend high-quality territories, a preference constrained by their need for water. Some researchers have classified this type of assortative mating as indirect precopulatory choice, while others have referred to it as "coincidental" mate choice (Clutton-Brock and McAuliffe 2009).

## Direct Postcopulatory Choice

Postcopulatory choice, also termed cryptic female choice due to the cryptic nature of processes occurring inside the female reproductive tract, is a mechanism of sexual selection that occurs during or after copulation. Direct postcopulatory choice occurs when females behaviorally or physiologically discriminate between the seminal products of different males, thereby influencing the likelihood of male fertilization after mating has already occurred. Most simply, this can be achieved by preventing complete intromission and ejaculation but can also occur after insemination through modification of the amount of sperm retained or stored in the female reproductive tract, or preferential usage of particular sperm.

Sperm ejection from the female reproductive tract is documented in many species, such as jungle fowl, rattlesnakes, parrots, and many species of insects. This can be a large portion of

the inseminate, such as in the soil nematode (*Caenorhabditis elegans*), where 42% of copulations resulted in active ejection of the ejaculate from the female's body (Barker 1994). Sperm ejection can also be more subtle, such as the gravitational flow back of only a portion of the seminal fluid. Coagulations of seminal fluids, called sperm plugs, are produced by many species in many taxa exhibiting polygynandrous mating and are used to retain the ejaculate within the female reproductive tract. There is ample evidence of females removing sperm plugs, thereby facilitating flow back. The peristaltic contractions of the vaginal walls that occur during female orgasm are also implicated as a mechanism by which females can influence the amount of sperm that flows back out of the vagina after mating. This process is noted in humans, and many nonhuman mammals, such as rabbits, cattle, and dogs. Differential sperm transfer within the reproductive tract to the location of sperm storage or ova fertilization is also a suggested mechanism of cryptic female choice.

Remating with a different individual soon after insemination is expected to decrease the probability of paternity in the first mating male, and the latency to remating is often associated with male quality. For example, female rats remate sooner after copulation with a low-ranking male than with a high-ranking male (McClintock et al. 1982). The order in which females mate with multiple males is well-documented to have significant effects on paternity in birds and insects, with the last mated male usually receiving a majority of paternity (Birkhead and Møller 1992; Thornhill and Alcock 1983). Once remated, female postcopulatory choice can occur through differential sperm storage, transport, or preferential use of the new male's sperm.

Throughout the process of fertilization, implantation, gestation, and after parturition, females can modify or terminate investment in ways that modify their reproductive success as well as that of their mate. Male traits that increase the probability of ovulation, or the number of eggs produced, would increase a male's reproductive success and be passed on to offspring. In mammals, hormonal changes within the female prepare

the uterus for implantation, which can also be differentially triggered by male behaviors. Once a zygote has been formed, spontaneous abortion (termed the "Bruce effect") can occur. This process is well characterized in mice following the introduction of a novel male but has also been observed in a wild setting in the gelada, a large-bodied, long-lived primate (Bruce 1960; Roberts et al. 2012). Finally, in species with parental care, females can differentially invest or terminate investment in offspring after parturition based on the quality of their mate; however, there are limited concrete examples of this mechanism of cryptic female choice occurring.

The genetic composition of sperm both within the same ejaculate and between the ejaculates of different males can also be the target of postcopulatory female choice. The "sperm receptor selection" hypothesis posits that receptors on the surface of sperm that lack self-reactivity will respond to chemical stimulation in the reproductive tracts of genetically dissimilar females, improving the probability of oocyte fertilization by sperm of dissimilar genetic composition (Ziegler et al. 2002). For example, in the gray mouse lemur (*Microcebus murinus*), researchers found that males with higher amino acid distances and fewer MHC supertypes shared with their mate sired more offspring (Schwensow et al. 2008). In addition to complementarity, certain genetic makeups may be favored regardless of female genetic composition. This preference for "good genes" is also suggested in the gray mouse lemur. All females favored sperm with greater microsatellite heterozygosity and more absolute total MHC alleles. In this case, however, it is difficult to determine whether this effect is due to intrinsic qualities of sperm with those genetic makeups or cryptic female choice.

## Indirect Postcopulatory Choice

The most commonly recognized mechanism of indirect postcopulatory female choice is that of sperm competition (Birkhead and Møller 1998). Sperm competition refers to the race that ensues between sperm from different males to fertilize the

egg in a multiply mated female. Females can play an active role in the extent of sperm competition occurring within their reproductive tract. Vocalizations given after copulations are hypothesized to communicate fertility and incite male-male competition for future matings. In primates, copulation calls appear to encourage mate guarding by dominant males, thereby decreasing sperm competition; however, copulation calls may also have the capacity to increase sperm competition by stimulating the interest of distant males and promoting promiscuous mating (Maestriperi and Roney 2005).

Female mating patterns and sperm competition have well-documented morphological and behavioral consequences for males. The relatively larger testis size observed in male primates living in polyandrous and polygynandrous mating systems is attributed to their increased need for sperm production as a consequence of sperm competition within the female reproductive tract (Harcourt et al. 1995). Selection on enhanced sperm production, semen coagulation, ejaculatory frequencies, and penile morphology are all likely influenced by the extent of sperm competition in the species. As a counter-strategy to sperm competition, males can produce a physical barrier to prevent the sperm of subsequent mating partners from fertilizing the females' eggs. In the Australian redback spider (*Latrodectus hasselti*), the male breaks off a portion of his copulatory organ inside of the female, blocking the entrance to her sperm storage organ from subsequent mating partners' sperm (Snow et al. 2006). Males can also engage in prolonged associations with fertile females, called consortships, to prevent mating and decrease sperm competition with other males.

Along with the quality of the sperm cells themselves, nutrients provided to the female by the male during or after mating may also correlate with paternity allocation and female fecundity. The hangingfly (*Hylobittacus apicalis*) female allows males to copulate with her only for as long as it takes for her to consume the male's food gift, with a larger food item equating to longer time spent in copulation, greater sperm transfer, and increased paternity (Thornhill 1976). The most drastic display of male

nutritional donation occurs when females cannibalize the male after copulating. In these species, females experience increased fecundity after copulations in which the female consumes the male. Larger males are more likely to be able to escape consumption after copulation, thereby females indirectly bias paternity toward smaller males (Thornhill and Alcock 1983).

## Conclusions

Even though this entry has organized female choice into four separate processes, it is likely that multiple mechanisms of female choice are present in the behavioral and psychological repertoire of any given organism. Both pre- and post-copulatory mechanisms may be at play, as seen in the female katydid (*Metaplastes ornatus*) that approaches only males with the most attractive calls, but stores ejaculate based upon the number of genital couplings the male performs (Helvesen and Helvesen 2004). Similarly, females can employ strategies of both direct and indirect choices. For example, female elephant seals (*Mirounga angustirostris*) modify their rate of calling depending on the dominance rank of their partner, so, while the call indirectly benefits the female by advertising fertility and inciting male-male competition, females are also actively adjusting their behavior based on male quality. In addition, if copulation calls incite mating by more than one male, indirect postcopulatory choice may then also subsequently occur via sperm competition (Cox and Le Boeuf 1977).

Much of what is known about female choice has been best explored in fish, insects, birds, and other organisms that are conducive to manipulatory experimental studies. Creativity in the design of experimental studies, particularly those in natural settings, will be needed in order to explore how intersexual selection acts on many animal groups. It will continue to be difficult to tease apart the extent of female choice relative to male coercion, especially when these tactics favor the same paternity outcome as seems to be the case in many mammalian species. Additionally, visual and auditory communication of mate quality has

been a major focus in studies of female choice, leaving a dearth of knowledge on the role of olfactory signals outside of a few taxa. As methods allowing exploration of genomic information become more efficient, the genetic underpinnings and consequences of female choice will be an especially interesting avenue of research. Until this information is available, it would be smart to assume that the processes observed in experimental studies of insects and other small organisms are likely not confined to those classes of organisms and are probably present in species of other taxa too.

## Female Defense Polygyny

Jordyn Truax

Oakland University, Rochester, MI, USA

## Synonyms

[Harem defense polygyny](#)

## Definition

Individual males control access to a large group of gregarious females.

## Introduction

There exists a range of potential mating systems among all species. These various mating systems have been classified to organize the terminology to better understand the evolution of mating systems (Emlen and Oring 1977). One of the overarching categories in this classification system, polygyny, includes any mating system where an individual male monopolizes access to a group of females. The grouping of females may occur by many means, such as behavioral or environmental pressures. Included in this category are resource defense polygyny, female defense polygyny, and male dominance polygyny. These categories are separately defined, but the distinction may not be straightforward in real-life scenarios.

## Female Defense Polygyny

Of the three types of polygyny, female defense polygyny is defined as when females gregariously group together and one male is able to monopolize these females from other males (Emlen and Oring 1977). The grouping of the females is possibly due to any number of reasons but does not include reproduction purposes. In this type of polygyny, the males may herd or retain the females within their territory through aggressive actions toward other opposing males. They must stop all opposing males' attempts in order to control access to the cluster of females.

## Distinguishing Female Defense and Resource Defense Polygyny

An issue observed in many species is that female defense polygyny often occurs in combination with male resource defense polygyny (Emlen and Oring 1977). Therefore, it can be difficult to distinguish between the two types of polygyny. It has been suggested that even though these may occur in combination, one may still be able to distinguish the value of the role that each system may play (Ostfeld 1987). It is first critical to assess if the males are in contact with the grouping females without being near any critical resources. If this is true, one may exclude resource defense polygyny. If it is not, then one must assess if the males will monopolize a resource in both the presence and absence of females. If males attempt to control this resource in the absence of females, then resource defense polygyny is the system employed. However, one must not rule out female defense polygyny if males adjust their territory after the arrival of females. Although female defense polygyny and resource defense polygyny may not be mutually exclusive, the classifications are still of empirical value.

## Conclusion

Female defense polygyny is a system of polygyny that requires individual males to monopolize the

access to a grouping of females. It is possible that this system may exist in conjunction with resource defense polygyny, but experimental evidence should be acquired to distinguish each system's role.

## Synonyms

Productiveness; The ability to conceive children

## Definition

Fertility is the ability of an individual to produce the offsprings by natural means. The root word of fertility is fero, which means “to carry, to bear.”

## Fertility

Fertility is the ability of an individual to produce the offsprings by natural means. The root word of fertility is fero, which means “to carry, to bear.” The term fertility is sometimes confused with fecundity, which defines the capacity of reproduction. Although fertility is a general term for all of the organisms, including plants, here we focused on human fertility. Louis Henry coined a term “natural fertility” which applied to the population where contraception is not used depending on the number of children that families have. The inability to conceive a child within a year or more with regular sexual intercourse is defined as infertility. The rate of fertility is an important factor to keep a close eye in the societies as many modern societies are going through fertility crisis (Caldwell and Schindlmayr 2003). The rate of fertility is a measure of health of a population, and to sustain a population, the balance of fertility rate is very important. The measurement of fertility rate is also important for policy makers and family welfare. Therefore the factors involve in modulation of fertility and indexes to measure a fertility rate are important to be discussed. The rate of fertility

can be influenced by various factors such as economic factors, social factors, cultural beliefs, and natural factor (Fernandez and Fogli 2006). One such social and cultural factor is gender division of labor in a family or household. Many studies found direct correlation between gender division in household and fertility rate. In one such study, it was found that women feel the burden of having a child in the household (Dommermuth et al. 2014). Altogether the factors that influence fertility can be categorized into mainly two types: proximate (direct) factors and background (indirect) factors (Bongaarts and Potter 2013).

## Proximate Factors

These variables influence fertility directly and also are intermediate factors. The ten different fertility variables, proposed by Davis and Blake (1956), which influence infertility, are directly given below and also can be categorized in 3 main groups, and each of them is described briefly.

- A. Factors affecting the exposure to intercourse:
  - (i) Age of marriage and entry into sexual unions
  - (ii) Reproductive period
  - (iii) The celibacy
  - (iv) Coital frequency
  - (v) Voluntary and involuntary abstinence
- B. Factors affecting exposure to conception:
  - (vi) Infertility
  - (vii) Contraception
  - (viii) Lactational infecundability
- C. Factors affecting parturition:
  - (ix) Miscarriage and fetal mortality
  - (x) Induced abortion

## Factors Affecting the Exposure to Intercourse

The higher exposure to intercourse increases the chance of becoming pregnant and results in higher fertility rate. In human society, childbirth is mainly considered after marriage. The average age of marriage differs in societies. The age of the marriage would be a major factor for the percentage of the reproducing female in a sexual

union in a population. If marriage age is lesser, then the more proportion of the female would enter in sexual unions, and that's how the year of the reproductive age also increases. There are many factors influencing the age of marriage such as education, economic development, cultural factors, etc. (Becker 1960).

Women can conceive for a short period of time called reproductive period. The culture factors also influence age of marriage and the time spent for regular intercourse. In many societies, there is a number of females who never enter into sexual unions and intently live in celibacy. All these factors influence the proportion of reproductive unions in a population and hence influence the fertility rate.

The fertility rate is influenced by the rate of coital frequency. Although the estimate on actual coital frequency is hard to find for a population, they have high impact on fertility. The higher the coital frequency, the higher the chance to conceive that leads to high fertility rate. The educated and working couples spend most of their reproductive time in separation due to separate work space and hence reduce the chance of pregnancy.

### Factors Affecting Exposure to Conception

Infertility is the inability to conceive child after having regular intercourse for at least a year and is considered a major factor which influences the exposure to conception. About 15% of couples are infertile, around the world. The infertility which is responsible by male and female's factors is almost 50–50%. The infertility is caused by different factors such as environmental toxicity, life habits, sexual diseases, and genetic factors. There are only 20–30% cases with known genetic factor; otherwise about 70% cases are idiopathic. One such factor which covers 15% genetic factor is Y chromosome microdeletions.

Contraception is a method which reduces the frequency of conception. Contraception is another factor that contributes to the exposure to conception which clearly can reduce the birth rate and clearly affect the rate of fertility of the society. In the late twentieth century contraceptions, mainly condom, hormone-based contraceptive pills, and germ cell sterilization, become tools to reduce birth rate. The revolution of the use of

contraception is highly correlated with decrease in fertility rate around the world. The use of contraception is also influenced by different factors such as education, sociocultural factors, and availability. The use of contraceptive methods is higher in educated women and higher in women who are living in urban areas. The use of contraceptive increases among women having enough number of children, but the criteria of enough number of children changed with different societies. There are also cultural factors such as some societies still think that children are god's gift and refuse to use contraception (Hayford and Morgan 2008). The methods used for contraception are also a concern for individuals for future risk of not conceiving a child. This fear reduces the use of hormonal-based contraception in many societies and was correlated with high birth rate. These factors influence the use of contraception in different societies and influence the fertility rate.

After delivery, women remain unable to conceive for a certain period of time. The duration of infecundability is dependent on the duration and the quantity of breastfeeding. The long duration of lactation delayed the normal menstrual cycle, and ovulation of breastfeeding mother differs among societies. The period of breastfeeding is lower in economically developed populations. The length of infecundability is longer in rural area and uneducated women (Campino et al. 2001). This is an addable factor which affects the conception and the rate of fertility among different societies.

### Factors Affecting Parturition

Miscarriage is a loss of pregnancy before 20 weeks of gestation. About 15% of pregnancies are unsuccessful because of miscarriage. The problem of miscarriage is correlated with different factors such as economic development, lifestyle, reproductive health, and pathological infections. Some women face recurrent miscarriage due to some known and idiopathic genetic disorders such as immunological disorders and chromosomal abnormalities, and its prevalence is approximately 5–8%. Induced abortions are another factor, which affects fertility rate. Its occurrence mainly depends on the practice to restrict childbearing and availability of contraception. Induced abortion is

practiced in almost all societies with different proportions. Induced abortion is motivated by different factors such as cultural and socioeconomic factor. One such cultural factor is dowry system which induces burden on girls' parents and leads to motivation of induced abortion of girl child. This gender-biased abortion leads to decrease in women proportion in a population and plays a meaningful effect on fertility (Hayford and Morgan 2008).

## Background Factors

This factor does not affect fertility rate directly. These factors are cultural, socioeconomic, and demographic variables such as age and marital status, place of residence, literacy status, occupation, religion, mass media exposure, wealth status, knowledge, the number of children already born, employment status, and income.

## Fertility Rate Measurement

Fertility can be measured by different methods in a population which refer to as fertility rate. Fertility rate is mainly estimated by two ways: first is periodic measure during a given period of time, and second is cohort measure within a given population.

The periodic measures include different estimates of the rate of fertility:

1. Crude birth rate (CBR) is defined as the number of live births during a year in a population of 1000 during the middle of the year.
2. General fertility rate is the number of live births stated in a time period per number of women aged 15–49 in the same period and expressed in 1000 women.
3. Total fertility rate is the total number of child born or likely to be born to a woman in her lifetime if she was to experience the prevailing age-specific fertility rates of women.

The abovementioned parameters are considered as proximate determinants (direct effect on fertility) such as union patterns, contraception, lactational amenorrhea and postpartum abstinence, pathological sterility, and abortion.

Bongaarts and Potter (2013) developed a model to establish the relationship between the total fertility rate and the proximate determinants of fertility and model known as Bongaarts model of proximate determinants. In this model total fecundity rate (TF) of women is considered the same, but their actual reproductive performance is modified by four major proximate determinants, marriage, contraception, induced abortion, and postpartum infecundability, i.e., denoted by  $C_m$ ,  $C_c$ ,  $C_a$ , and  $C_i$ , respectively. So, the equation is as follows:

$$TFR = C_m \times C_c \times C_a \times C_i \times TF$$

where TFR = total fertility rate

$C_m$  = index of marriage ( $C_m = 0-1$ ; equals 1 if all women of reproductive age are married and 0 in the absence of marriage)

$C_c$  = index of contraception ( $C_c = 0-1$ ; equals 1 in the absence of contraception and 0 if all fecund women use 100% effective contraception)

$C_a$  = index of induced abortion ( $C_a = 0-1$ ; equals 1 in the absence of induced abortion and 0 if all pregnancies are aborted)

$C_i$  = index of postpartum infecundability ( $C_i$  ranges from 0 to 1; equals 1 in the absence of lactation and postpartum abstinence and 0 if the duration of infecundability is infinite)

TF = total fecundity rate

Total fertility rate of India is 2.33 births per woman (2016). Africa and Somalia have high TFR (6.95 children per woman), whereas South Korea has low TFR (1.1 children per women).

## Conclusion

Fertility has a major impact on the socioeconomic condition of a country. To regulate the fertility rate in a country, it is very important to study the direct and indirect parameter carefully (Mahjabeen et al. 2011). The following methods could be used to regulate fertility:

- (a) Contraception-related information and campaigning should be re-emphasized, as it is a direct parameter that affects fertility rate.
- (b) After achieving the desired number of children, couples should be encouraged for sterilization to avoid unwanted pregnancy.
- (c) Awareness-raising programs should be undertaken in order to prevent female child or adolescent marriage – especially among illiterate people and in the rural areas which will help to increase the age at marriage of women.
- (d) Due to traditional sociocultural background, open consultation about reproductive health issues should be encouraged. Education system and media can play important role in overcoming this problem.

## Definition

The term fetus can be defined as the unborn offspring in the uterus representing the post-embryonic stage of development until birth.

## Introduction

Fetus is a Latin word that symbolizes “pregnancy, childbirth, offspring.” Fetus is the unborn vertebrate that has reached later stages of development exhibiting distinctive features of a mature animal. In a fetus all major structures (organs and their precursors) are already formed and they keep growing, differentiating, and developing.

Among glands, thyroid is known to develop first by 4th week of gestation when adrenal cortex can be seen and parathyroids begin to develop (Gardner and Shoback 2011). At the same time, fetal pancreas starts to develop but insulin secretion begins around 12th week of gestation. Reproductive system starts developing from 4th to 5th week of gestation. During this duration, a cavity of ectodermal cells of the oropharynx known as Rathke’s pouch forms and later gives rise to the anterior pituitary gland. Hematopoiesis starts in the yolk sac and then by 10th week of gestation, the function is transferred to liver. Later, it goes to spleen and bone marrow subsequently. Early in development fetal erythrocytes are megaloblastic which later become normoblastic near parturition. Fetal RBCs live for about 80 days. Leukocytes production in fetus begins at 8 weeks of gestation from thymus and spleen (Percival et al. 1980; Evans and DeFranco 2014).

Development of brain starts with neurulation (formation of neural tube from ectoderm) just after gastrulation in all vertebrates. During gastrulation the

three germ layers are formed namely the endoderm (the inner layer, which gives rise to the gut), ectoderm (the outer layer, which gives rise to skin and the nervous system), and mesoderm (the middle layer, which later gives rise to rest of the organs). A group of cells from the mesoderm forms notochord (notogenesis). In the gestational week 3, underlying notochord induces the ectodermal cells just above it to become neuroectoderm. This forms neural stem cells giving rise to neural plate, from where the complete nervous system emerges (Fig. 1).

## Fetal Development in Humans

In humans, fetal period is four times longer than the embryonic period, *i.e.*, between weeks 9–37 following fertilization. In clinical context, it is delineated as second and third trimester. During this period highest rate of growth occurs *per se* as well as in various organs. The organ systems that started to form (organogenesis) during embryonic phase persist to develop and differentiate further in an age-dependent manner. Different molecular switches control organ system development in the fetus. For example, a DNA-binding protein, known as sex-determining region Y (SRY) protein, encoded by *SRY* gene initiates male sex determination. During fetal period, the urogenital system differentiates into either male or female pattern accordingly. Additionally, the

**Fetus, Fig. 1** Perinatal development showing the stage of fetus. A fetus develops from the embryo and after birth it is called as offspring. During fetal period most organs get fully developed and functional

**Fetus, Fig. 2 Human pregnancy timeline.** Embryogenesis precedes fetal development, which occurs since week 9 till the birth of the offspring. On an average, childbirth occurs after completion of 9 months but one can see, birth classification states it to be preterm if occurs around 7th or 8th month whereas it is called postmature if it is around 10th month of gestation (Hägström 2014) (Reproduced with permission)

gastrointestinal tract and endocrine system starts functioning during this period. Brain keeps on growing and differentiating into more complex structure during the fetal period. While the brain keeps improving itself in the postnatal period, respiratory system completes the differentiation process just before birth (Moore and Persaud 2003) (Fig. 2).

## Fetal Brain Development

Brain is one of the first organs to start forming in an embryo and certainly the last to completely develop functionally. This long duration is required for neural differentiation, making complex network of neurons and interconnecting neural pathways controlling all organ systems. The nervous system continuously grows and increases in its complexity. By week 3 of embryonic development (gestational week 5), neural groove and folds are visible and hence

neurogenesis commences. During 4th week, the development of central nervous system (also known as CNS) initiates as a neural plate which folds to form a groove and then the neural tube (Hill 2017). The stem cells from the neural tube give rise to majority of cells in the nervous system namely neurons and glia. Later on these cells differentiate into different types with varied shape, structure, and function according to the microenvironment milieu. At cellular level different neurons are born that migrate and differentiate, extend processes, and few die (programmed cell death) during fetal period to accommodate different functions and rectify the assembly of nervous system.

By the end of week 4, spinal cord and the primary brain vesicles are formed namely Prosencephalon (forebrain), Mesencephalon (midbrain), and Rhombencephalon (hindbrain). By next week the secondary vesicles are formed: prosencephalon gives rise to telencephalon and diencephalon; mesencephalon remains same as secondary

**Fetus, Fig. 3 Human fetal brain in the later stage.** *Left* dorsolateral view of a human fetal brain at crown-rump length (CRL) of 240 mm. Few major gyri and sulci start appearing as compared to the embryonic brain and hence

the Sylvian fissure becomes prominent. The scale bar shows 1 cm length (Hill 2017) (Reproduced from [https://embryology.med.unsw.edu.au/embryology/index.php/File:Human\\_brain\\_growth\\_01.jpg](https://embryology.med.unsw.edu.au/embryology/index.php/File:Human_brain_growth_01.jpg))

vesicle; and rhombencephalon gives rise to metencephalon and myelencephalon. These secondary vesicles give rise to different adult brain structures and the major ones are: Telencephalon gives rise to cerebrum (cortex), amygdala, hippocampus, hypothalamus, pituitary, basal ganglia, lateral ventricles whereas, diencephalon differentiates into epithalamus, thalamus, subthalamus, pineal and third ventricle. Mesencephalon forms the cerebral peduncle, tectum, pretectum, and cerebral aqueduct. Metencephalon differentiates into cerebellum and pons whereas medulla oblongata evolves from myelencephalon (Hill 2017) (Fig. 3).

## Factors Affecting Fetal Development

The development during the embryonic and fetal stages of gestation is called prenatal development. By 11th week of gestation, an embryo acquires its basic form and from then it is known as fetus. At this stage of fetal development many of the organs are fully developed. If there are any genetic abnormalities in the embryo/fetus, it gets spontaneously aborted in the first trimester. Fetus drives all of the requirements from the mother therefore, perinatal nutrition is very important. A pregnant woman needs an increase of calories by 300 kcal/day and proteins by 70–75 g/day as compared to regular diet. For proper neural development and avoiding neural tube defects, a mother should also increase the dosage of vitamin B12 and folate. Such supplementation helps in proper growth of the fetus. At this stage the concept of fetal origins (programming) of adult disorders (FOAD) (Barker 1990; Last 2007) is very crucial to understand. Evidences show nutritional insufficiencies during fetal development, program for metabolic syndrome in later life (Lakshmy 2013; Ghosh et al. 2017).

Prenatal developmental period, that is critical for the growth and development of the embryo and fetus, is susceptible to exposures to various internal or external factors, like:

1. Nutritional insufficiencies, *e.g.*, vitamin B12, folate, *etc.*
2. Drugs (substance) of abuse and alcohol (fetal alcohol syndrome), *e.g.*, cocaine, amphetamines, lysergic acid diethylamide (LSD), phencyclidine (PCP), *etc.*
3. Toxins, *e.g.*, lead, polychlorinated biphenyls (PCBs), tetrachloroethylene (PERC), bisphenol A (BPA), dichlorodiphenyltrichloroethane (DDT), phthalates, chlorpyrifos, arsenic, mercury, fluoride, *etc.*
4. Radiation exposure above 200 mSv, *e.g.*, x rays, fluoroscopy, or radiation therapy
5. Infections, *e.g.*, candidiasis, cytomegalovirus, rubella, *etc.*

## Conclusion

Fetus is the postembryonic stage in the prenatal development of viviparous animals and lasts till the birth of the organism.

## Fidelity

Rachel E. Watson-Jones  
Dell Technologies, Austin, TX, USA

### Definition

The exactness with which an agent reproduces the observed behavior of another individual or group. Copying (also called imitative) fidelity can be thought of as a spectrum from high to low and encompasses various social learning strategies.

Copying fidelity and imitation have been characterized in a variety of ways throughout the literature on social learning. Research on social learning has primarily come from comparative programs focusing on how children, and other species (primarily apes and monkeys) learn from others to acquire problem-solving, instrumental skills. Much of the previous literature has examined the physical-causal information required to allow children, and other animals, to accurately copy an instrumental action sequence. The focus on the role of physical-causal reasoning in social learning led to attempts to define social learning mechanisms based on what features of an action sequence children, and other animals, accurately replicate. Much of this literature has ascribed a central role to children's ability to read a demonstrator's intentions toward a physical-causal end-goal. There are alternative theories that

diminish the role of intention reading in copying fidelity as well as evidence that copying fidelity is increased or decreased based upon the nature of the observed task. When an action sequence is interpreted as conventional and based in social stipulation, copying fidelity is increased, and when an action sequence is interpreted as instrumental, copying fidelity may be decreased when a clear goal is present. The tendency to copy conventional behavior with high fidelity may be a uniquely human trait associated with the importance of engaging in conventional behavior for group membership.

### Theories of Social Learning Strategies Associated with Copying Fidelity

Tomasello and colleagues (Tomasello 1990, 1996; Tomasello et al. 1993, 2005) proposed a distinction between social learning via imitation and social learning via emulation based upon what an observer is proposed to be attending to when replicating behaviors: the behavior of another (imitation) or the changes in the environment caused by the behavior of another (emulation). An individual who is emulating will seek to reproduce the same change in the environment with little attempt to copy the actual actions of a model. In this way, the observer may be said to be learning something about the causal effect of another's actions, which they may seek to reproduce using their own strategy. Early research in this field sought to examine the differences between social learning strategies used by young children and apes.

One of the first paradigms used to examine differences in imitation and emulation between children and chimpanzees was the artificial fruits task (Whiten et al. 1996) in which a demonstrator opened a "fruit" by removing components of the apparatus using one of two possible techniques. Results demonstrated that even through chimps would copy observed methods of removal on the artificial fruit, young children (18–24-months-old) imitated the demonstrated action with higher fidelity. More recently, Tennie et al. (2006) used an apparatus that could be opened either by

pushing or pulling a door to retrieve a reward. They tested children (12–24-month-olds) and great apes in one of four conditions: (1 & 2) watching a demonstrator either push or pull the door to retrieve the reward or (2 & 3) watching the door open by itself either inwardly or outwardly on its own (“ghost” control). They found that apes tended to retrieve the reward using their own strategies and children tended to use the method they saw demonstrated. These results were taken to indicate that children more readily use demonstrated actions to inform their goal-directed behavior.

In the framework of this research, imitation requires an understanding of another’s intentions and goal-directedness including attention to and replication of the model’s actions used in attaining the goal. This intention understanding also distinguishes imitation from mimicry in which reproduction of body movements is said to occur at the sensory-motor level and not to involve cognitive processes of intention attribution. Imitation, involving an understanding of another’s goal and the actions used to attain the goal, can be employed as an efficient learning strategy even when causation is not apparent. Alternatively, Heyes (2001) has argued that proposing a dichotomy between mimicry and imitation conflates a model’s intention and the observable outcome of the model’s actions as goals. Heyes and colleagues (Bird et al. 2007; Leighton et al. 2010) have presented evidence in support of the argument that imitation is not reliant on the coding of goals, either as physical end-states (Bird et al. 2007) or as mental states or intentions (Leighton et al. 2010).

Imitation has also been described as a process in which aspects of an action sequence are selectively reproduced based upon a rational assessment of the physical-causal information available (Gergely and Csibra 2003, 2006). This requires an understanding of the means, goals, and subgoals in a hierarchical manner (Bekkering et al. 2000). If end-states or “final goals” are present, these become the most salient aspects to be copied and copying fidelity will be low. When end-goals are not apparent or salient, however, an observer will copy the action styles, seemingly because they

view the action styles as the only apparent goal and copying fidelity will be high (Carpenter et al. 2005).

Whiten and colleagues (Whiten and Ham 1992; Whiten et al. 2004) have termed the phenomenon of copying the end-state, or goal at the top of the action hierarchy, “goal emulation.” Goal emulation involves an observer seeking to replicate a model’s goal, while not necessarily using the same means to attain the goal. Imitation, end-state emulation (including both result and goal emulation), and object movement reenactment (OMR) constitute forms of copying the behaviors of others. Imitation is defined as copying the form of an action. Object movement reenactment involves an observer attending to and copying what an object does, or what is done with an object. End-state emulation includes emulation of results and goals. Heyes (2001) distinguishes “imitation” from “emulation” as involving the copying of body movements and copying of object movements, respectively. Copying can be viewed as a continuum containing end-state emulation, moving to object movement reenactment, with the extreme end of the continuum involving copying body movements (Whiten et al. 2009).

When an observer emulates, they must understand and work out the causal links involved in a behavioral sequence in order to attain the same results as the model using individual means. When using an imitative strategy, however, the observer need only reproduce the model’s actions closely enough to replicate the results, without needing to fully appreciate the causal links involved. This would be a good strategy to employ when the causal links of an action sequence are difficult to discern, and possibly when there is no apparent end-goal, or result, to achieve (Horner and Whiten 2005).

In a series of experiments (Horner and Whiten 2005), the availability of causal knowledge was manipulated across conditions to assess the strategies children and chimpanzees use in reenacting demonstrated actions. Children and chimpanzees were shown a demonstration of how to use a tool to retrieve a reward from a puzzle-box. The action sequence demonstrated both causally relevant and

irrelevant actions in retrieving a reward from the box. In one condition, the subjects were shown the demonstration on a transparent puzzle-box, in which it was clearly visible which actions were relevant and which were irrelevant to retrieve the reward. In the second condition, the subjects were shown the same actions on an opaque puzzle-box, in which it was not clear which actions were necessary to retrieve the reward. Chimpanzees were more likely to discard the irrelevant action in the transparent condition and were more likely to include the irrelevant actions in the opaque condition. The authors concluded that chimpanzees are likely to employ an emulative strategy when causal knowledge is available and an imitative strategy when causal knowledge is absent or ambiguous (Horner and Whiten 2005).

Importantly, children were found to reproduce both causally relevant and irrelevant actions with a high degree of fidelity in both the transparent and opaque conditions (Horner and Whiten 2005), demonstrating what has come to be termed “over-imitation” (McGuigan et al. 2007; Lyons et al. 2007) or “overcopying” (Whiten et al. 2009). These findings indicate that children are likely to imitate regardless of their knowledge of the causal relations involved in a problem-solving task. These results may be due to children’s selective attention to the actions, and therefore intentions and goals, of the demonstrator (Horner and Whiten 2005). Thus, the children may have carried out all of the demonstrator’s actions, even if they were aware that some of the actions were causally irrelevant, because they viewed the demonstrator’s actions as purposeful (Horner and Whiten 2005; Williamson and Markman 2006). Research suggests that knowledge of the causal relationships involved in a problem-solving task does not detract from the fidelity of copying in young children’s matching behavior.

The main argument in the majority of the social learning literature is that imitation affords the highest level of copying fidelity, which is required for the transmission of behavior and cultural evolution. Whereas there is evidence that children can copy based on goal hierarchies and intention reading, much of human culture consists of not only causally, but also cognitively, opaque practices.

Therefore, there must also be a mechanism that allows for imitation that is not reliant on the identification of goals based on an inference of intentions.

### **Copying Fidelity and Conventional Versus Instrumental Interpretations of Behavior**

Much cultural learning in human societies is motivated by affiliative goals that guide the acquisition of conventional, ritualistic behavior rather than instrumental behavior. Many of the conventions children need to learn to become competent members of their cultural community involve high-fidelity copying and the replication of behavior for which physical-causal rationales are never provided and never sought. High-fidelity copying is crucial for learning basic socially stipulated behavior. Young children often implicitly engage in the gestural, postural, and overt (yet opaque) actions of older children and adults. Children navigate social learning opportunities by using physical, situational, and social cues to determine when actions are based in physical-causal reasoning and when actions are based in conventionality and social stipulation (Legare et al. 2015; Legare and Watson-Jones 2015; Watson-Jones and Legare 2016).

Whereas previous research has demonstrated that intention reading likely plays a part in determining why an individual may imitate in a given situation (Horner and Whiten 2005; Tomasello et al. 2005), there is evidence that there is not a special relationship between imitation and intention reading (Leighton et al. 2010). The associative sequence learning (ASL) model (Heyes 2001, 2005, 2013; Heyes and Ray 2002) proposes a direct connection between a visual and a motor representation of any given action. The ASL model allows for imitation that is often not deliberate or “rational” and will often result in over-imitation – high-fidelity copying. This concept of imitation does not require an understanding, or inference, of a model’s goal (Heyes 2013).

Research has demonstrated that when children are presented with an action sequence that has no

clear end-state, or physical causal rationale, copying fidelity is increased. Children were either presented with a demonstration of an action sequence that contains a distinct end-state that is different from the start-state (instrumental condition) or a video demonstration of an action sequence in which the start- and end-states are equivalent (convention condition). Both of the action sequences used in the study were causally opaque. The presence of an end-state that was different from the start-state in the instrumental condition, however, cued the children to the possibility of a potentially knowable causal structure. The start- and end-state equivalency of the convention condition biased the children's interpretation of the action sequence towards an interpretation of conventionality and significantly increased copying fidelity. These results indicate that when physical-causal goals are absent, children may be more likely to interpret actions as socially stipulated behavior (Legare et al. 2015; Watson-Jones et al. 2014).

Children use cues, such as the presence or absence of end-states, consensus between actors, synchrony, language, etc., to navigate cultural learning and determine when actions are based in instrumentality and when they are based in social convention (Clegg and Legare 2016; Herrmann et al. 2013). Therefore, "overimitation" may not even be an appropriate term for copying social convention, in which strict adherence is typically expected and observed. High-fidelity copying is plausibly driven by social motivations, more specifically a propensity to engage in affiliative interaction with group members. Humans have relied on group living for survival throughout evolutionary history (Brewer 2007; Buss and Kenrick 1998) and engage in unique forms of collaborative interactions that require a motivation to maintain affiliation and good standing within a group. Research has demonstrated that when affiliative goals are increased, children increase their copying fidelity (Over and Carpenter 2009), especially of action sequences cued as conventional and associated with an in-group (Watson-Jones et al. 2014, 2016). Whereas social motivations likely play a role in

children's copying fidelity of instrumental skills, socially motivated copying may be essential to learning the social conventions of one's group (Legare and Watson-Jones 2015; Watson-Jones and Legare 2016; Wen et al. 2016).

### Definition

Shortly after birth or hatching, the young of some animals, usually of **precocial** species, learn to recognize their mother and/or other social partners (e.g., siblings) by simply being exposed to them, and subsequently exhibit affiliative responses to them. Filial imprinting is thus a form of perceptual learning that serves to confine social preferences and social attachment to a specific object (or class of objects) as a result of exposure to that object (Bateson 1990).

### Introduction

Filial imprinting was known from antiquity and exploited by farmers and breeders. It was originally described in the scientific literature by Douglas Spalding and later studied and popularized by the ethologist **Konrad Lorenz** (1935).

Although imprinting phenomena have been described in mammals, they have been mostly studied in birds. Filial imprinting is most readily apparent in **precocial** species, i.e., those whose young are relatively mature and mobile soon after birth or hatching. Domestic chicks and ducklings have thus been mainly used for research on filial imprinting, though it has been described also in altricial species.

Lorenz (1935) believed that filial imprinting determines adult sexual preferences. Actually, filial and **sexual imprinting** appear to be two different (though partially overlapping) processes. Apart from the difference in the expression of behavior (approach and affiliative responses in filial imprinting versus courtship

and sexual behavior in sexual imprinting) they differ in timing, for sexual preferences are expressed later than filial preferences and have a longer period of exposure. Moreover, sexual preferences are affected by experiences occurring after filial imprinting is completed (review in Bolhuis 1991).

Lorenz (1935) also believed that the function of imprinting was to develop species recognition but it has become apparent that the main outcome of imprinting is the formation of a recognition memory of the specific individual (either a living animal or an artificial object) to which the animals have been exposed to. This is not necessarily in contrast with the fact that imprinting mediates species recognition, for evidence suggests that the two hemispheres of the chick's forebrain could attend separately to these functions (below).

### Imprinting as a Learning Phenomenon

Imprinting has been traditionally considered different from associative learning because of the absence of an explicit reward and because it is irreversible. There have been attempts, however, to argue that the imprinting object itself, or some of its features (e.g., motion) may act as reward or as unconditioned stimulus (as in Pavlovian associative learning). However, evidence suggests that phenomena observed in associative learning are small (e.g., blocking) or absent at all (e.g., overshadowing) in filial imprinting. Besides, neurobiological studies in which brain areas involved with filial imprinting were lesioned (see below) revealed a dissociation: chicks unable to imprint on an object because of the brain lesion were nonetheless capable of associative learning on the same object (i.e., to press a pedal in order to see the object as a reward) (see Bateson 1966).

As to irreversibility of imprinting, it has been shown that "secondary imprinting" can be observed. After learning on a particular object, chicks can, for instance, reverse their preferences for that object following exposure to a new one. However, it seems that memory of the original object ("primary imprinting") is not lost and can reappear under certain conditions, thus showing

that there is indeed some irreversibility, though in a less strong form as originally theorized.

Imprinting differentiated from observational learning as well because, instead of being available throughout the lifespan, it is exhibited in a limited period of life, what Lorenz (1935) called a **critical period**. In the youngs of domestic fowl (*Gallus gallus domesticus*), for instance, imprinting usually occurs within 24–48 h from hatching. However, this time window can extend for few more days, in case a proper stimulus is not immediately available (Bolhuis 1991). For instance, if domestic chicks are maintained in the dark, imprinting can be obtained up to about day 8 after hatching. This flexible period, that has the characteristics of a self-terminating process, is known as **sensitive period**. It has been discovered that the thyroid hormone  $T_3$  is implicated in controlling the timing of the sensitive period. In domestic chicks, imprinting causes fast inflow of  $T_3$  in the vascular endothelial cells in the brain. In non-imprinted chicks whose sensitive period is ended, administration of  $T_3$  allows imprinting to occur, re-opening the sensitive period (Yamaguchi et al. 2012).

Bateson (1990) argued for a basic difference between imprinting and associative learning, with the associative learning being mainly involved in extracting the causal structure of the world and imprinting implicated in building up perceptual categories. While timing is crucial to establish cause-effect relationships (for causes should come before effects), the order of the stimuli should not be important to establish categories in filial imprinting. Order could be important, however, if associated with different probability of occurrence. Recent evidence shows a sensitivity of chicks to ordered transitional probabilities of different stimuli images during imprinting (Santolin et al. 2016). As Bateson (1990) noticed, in a natural environment chicks must recognize their social partners independently of the visual perspective and, given that different views of social partners likely follow one another over short periods of time with a certain ordering, these abilities can be useful to build up a representation of the whole social companion.

Although imprinting can be obtained with either naturalistic (resembling to a conspecific) or artificial objects, evidence has accumulated for the existence of biological predispositions that act as a sort of guidance or canalization system to direct the newborn animals' attention, and in turn exposure important to determine imprinting, towards the objects that are more likely to be social partners. Predispositions for animacy cues (that make apart animate vs. non-animate objects) have been described in newly-hatched chicks and comprise preferences for face-like stimuli, biological motion stimuli, self-propelled objects, and objects that move with changes of speed (review in Di Giorgio et al. 2016).

## Neural Bases of Imprinting

A restricted part of the forebrain, the intermediate and medial mesopallium (IMM), has been identified in the domestic chick as a plausible memory store for visual imprinting. Ablation of the IMM before exposure to an imprinting object prevents imprinting, ablation after exposure makes chicks amnesic, i.e., unable to discriminate between the exposure object and a novel object. Imprinting is also associated with pre- and postsynaptic changes in the IMM, and neurons that respond selectively to the imprinting object have been described in this area (Horn 2004).

Auditory imprinting, with acquired preferences following exposure to the maternal call of a hen, seems to be associated with activation of a closed area, the medio-rostral nidopallium/mesopallium (MNM). Changes in synapses and electrophysiological activity related to imprinted acoustic stimuli have been documented.

A **brain lateralization** has been described in the neural bases of imprinting memory, with respect to both the temporal and the functional aspect (Rogers et al. 2013). It appears that three different storage systems are formed following exposure to an imprinting object: one in the left IMM, one in the right IMM, and a third one in an unknown location after about 6 h from exposure. The left IMM appears to be responsible for the long-term storage of information about the

imprinting stimulus, whereas the right IMM would act as a sort of buffer store to permit storage in another site outside IMM. Studies with domestic chicks tested under monocular conditions of vision (which in birds with laterally placed eyes largely confine information processing to the contralateral hemisphere) and single cell recordings in the IMM suggest functional differences between storage sites in the two hemispheres. It has been suggested that encoding of the general and invariant features of the imprinting object occurs in the left hemisphere, whereas encoding of the unique and variant features of individuals is carried out in the right hemisphere (Rogers et al. 2013). This would guarantee both fast responses to social partners as distinct by other types of stimuli (e.g., food, predators) and considered responses within the category of social partner (e.g., individual recognition of a sibling).

## Imprinting as a Tool to Study Animal Cognition

Other than being an important scientific topic in itself, imprinting has recently proven to be useful to investigate a variety of early knowledge mechanisms in young birds. For instance, it has been employed to study early knowledge of the intuitive physics of objects, geometry, and arithmetic (see Vallortigara 2012). It has also been shown that newborn chicks (Versace et al. 2017) and ducklings (Martinho and Kacelnik 2016) are able to extract abstract patterns present in the imprinting object. For instance, chicks imprinted using either patterns with two identical items (XX) or patterns with two different items (XY), were able to extract and generalize the abstract XX or XY relation presented in the imprinting stimuli to novel objects. All this suggests that, in spite of its apparent behavioral simplicity, filial imprinting is associated with quite abstract conceptual reasoning.

[Evolution](#); [Genetics](#); [Natural selection](#)

Ronald Aylmer Fisher (1890–1962) was the most original evolutionary biologist of the twentieth century. Fisher was also the greatest statistician of all time, and the majority of his publications were devoted to statistics rather than to evolution or genetics. His life and work have been the subject of many articles and a full-length biography (Box 1978). This entry summarizes his major contributions to evolutionary biology.

There was, of course, a strong connection between his statistical and biological interests. His first major paper on genetics (Fisher 1918) applied the principles of Mendelian genetics to measures of the resemblances between relatives with respect to continuously varying traits (regression and correlation coefficients), which had been developed by Francis Galton and Karl Pearson (Provine 1971). Fisher showed that (contrary to claims by Pearson), the values of these measures for traits like human height were compatible with the hypothesis that variability is caused by the joint effects of multiple Mendelian loci and nongenetic causes.

While this problem was independently studied by Wilhelm Weinberg in 1910 and Sewall Wright in 1921 (Provine 1971), Fisher's formulation formed the basis for most subsequent theoretical work on the genetics of quantitative traits. He

introduced the term “variance” for the mean of the squares of deviations from the mean, and the concept of breaking the total genetic variance down into its component parts, with the “additive” component playing the main role in resemblances between relatives, whereas the “dominance” and “epistatic” components (referring to nonadditive effects of alleles at the same genetic locus and among alleles at different loci, respectively) make smaller contributions. As enshrined in Fisher's famous and much-debated “Fundamental Theorem of Natural Selection” (Fisher 1930b, 1941), the additive genetic component of variance in fitness determines the rate of change in mean fitness of a population due to allele frequency changes.

In 1922, Fisher made several pathbreaking contributions to population genetics theory, in a paper motivated by his wish to understand the causes of quantitative trait variability (Fisher 1922). First, he studied the stable equilibrium in allele frequency in a large population that arises when the heterozygote at a locus with two alternative alleles has a higher fitness than the two homozygotes. This was the first demonstration that selection could act to preserve variability, as opposed to causing one type to replace another, a very important shift in thinking about the workings of natural selection. He also analyzed the dynamics of allele frequency change when one allele has a net advantage over the other, for some special cases with respect to the level of dominance of the fitness effects of the alleles. In addition, he introduced the use of probability generating functions for analyzing the survival of a new mutant gene in a large population, later employed by J.B.S. Haldane to derive the widely used result that a mutation with a small selective advantage of  $s$  over the prevailing type has a probability of approximately  $2s$  of surviving random loss from the population (Provine 1971).

Fisher also introduced the diffusion equation method for studying the probability distribution of allele frequencies, generated by the random sampling of alleles in a finite population (now called “genetic drift” following Wright's terminology), analyzing both purely neutral cases and cases with selection, and asking how much variability could be maintained with a given supply of new

mutations. Fisher made an error in using a transform of the allele frequency, incorrectly assuming that the expected change in the transformed variable due to drift was zero. This led him to claim that the rate of loss of variability due to drift is  $1/(4N)$ , where  $N$  is the size of the breeding adult population of a diploid, randomly mating organism. Wright was stimulated by Fisher's work to initiate his own study of the problem and found the rate to be  $1/(2N)$ , leading to an extensive correspondence with Fisher (Provine 1971).

In his 1930 paper, Fisher reworked and extended his approach, in what is one of the most brilliant papers in population genetics (Fisher 1930a), providing results that form the theoretical basis for current studies of molecular evolution and variation. Of especial general significance was his formula for the probability of fixation of a mutation in a finite population of size  $N$ . Fisher's conclusion was that a very weak intensity of selection (of the order of  $1/N$ ) is sufficient for a new mutation to behave as though the population is infinitely large. This was of considerable historical importance in combatting the then widely held view that natural selection was not capable of explaining adaptive evolution (Provine 1971).

His early work was synthesized in *The Genetical Theory of Natural Selection*, the most important book on evolution after *The Origin of Species* (Fisher 1930b). It opens with a discussion of the importance of Mendelian, particulate inheritance for evolution, pointing out that the Mendelian mechanism preserves genetic variability. This removes the difficulty faced by Darwin, whose belief in blending inheritance led him to postulate a high rate of input of new variability each generation by the inheritance of acquired characters, in order to counteract the loss of variability under blending inheritance. Fisher argued that random mutations in Mendelian genes provide a sufficient supply of variability on which selection can act, a fundamental tenet of what has become known as the Modern Synthesis of evolution. This set the stage for a series of chapters exploring the consequences of Mendelian inheritance for the evolutionary process.

Together with contemporary work by Haldane and Wright (Provine 1971), Fisher's ideas provided a coherent theory of the mechanism of

evolution, forming the core of research in evolutionary genetics down to the present day. His concepts of a "runaway process" of the evolution of female mate choice of male secondary sexual characters, and selection for equal investment by mothers into male and female offspring, have been extremely influential. Several of Fisher's other important conclusions were communicated in a few sentences, such as his anticipation of the theory of kin selection, and arguments for the evolutionary advantages of sexual reproduction and for the evolution of close linkage between polymorphic genes that interact in their fitness effects; they are thus often overlooked.

In discussing the evolution of mimicry as an example of the evolution of a complex adaptation involving coordinated changes in several traits (Chapter 7), Fisher proposed that the effects of alleles at a segregating locus could be modified by mutations at other loci, so that a relatively small initial difference between polymorphic mimetic and nonmimetic forms would become much greater over time. This greatly influenced subsequent empirical research into mimicry. Fisher was the first to propose the idea of the inverse dependence of the fitness of a genotype on its frequency in the population as a mechanism for maintaining genetic variability, noting that this occurs when predators have to learn to avoid eating members of a harmful species that is being mimicked by a harmless, edible species. Not surprisingly, Fisher was probably the most explicit advocate of the neo-Darwinian view of stepwise adaptive evolution. He developed a geometric model of the fitness effect of a mutation affecting a multidimensional trait, which he used to argue that mutations with small effects are more likely to confer a selective advantage than ones with large effects (Chapter 2); again, this model is widely used in contemporary research.

Fisher's theory of the evolution of dominance also involved modifiers; he proposed that mutations with deleterious fitness effects when heterozygous with the wild-type allele at the same locus would create selection on modifier loci to reduce these fitness effects, explaining the fact that mutations with major phenotypic effects are usually recessive. This led to a controversy with Wright, who proposed an alternative explanation based on

enzyme kinetics (Provine 1971). Most current researchers believe that Wright's view has been validated with regard to rare, deleterious mutations, although dominance modification probably plays a role in the evolution of genetic polymorphisms that involve major phenotypic differences, such as mimicry.

Fisher also disagreed with Wright about the importance of drift in a species divided into many small subpopulations, which formed the basis of Wright's "shifting balance" theory of adaptive evolution. Fisher rejected the possibility that genetic drift could be a significant evolutionary process on the grounds that most species have population sizes in the millions or thousands of millions, so that even minute average selective effects should be able to control the frequencies of variants. Later, Kimura argued that much variation and evolution at the DNA and protein sequence level reflects the action of drift on selectively neutral or nearly neutral mutations. A good deal of current research into molecular variation and evolution seeks to test the predictions of neutral models against alternative models that invoke selection – the Fisher-Wright controversy thus continues to resonate in modern evolutionary biology.

Most of Fisher's general views on evolution were developed by 1930, with some additions in the 1958 second edition of *The Genetical Theory of Natural Selection*. These included an attack on the idea that adaptive traits can evolve because of an advantage to the species rather than the individual, which had unfortunately become widely accepted because of the writings of C.D. Darlington and G.L. Stebbins on the evolution of genetic systems and breeding systems. He continued to make characteristically ingenious contributions to evolutionary genetics theory throughout his life, the most notable probably being his analysis of the wave of advance of a favorable mutation through a population occupying a linear habitat (Fisher 1937). He was the first to understand that there can be selection on a trait such as the frequency of self-fertilization purely through its effect on the transmission of alleles from one generation to the next (Fisher 1941). He also invented the theory of "junctions" in the composition of chromosomes, reflecting sites where a recombination event in an ancestral

individual causes a switch from maternal to paternal material (Fisher 1954). This has recently become an important tool for statistical analyses of DNA sequence data from natural populations.

Fisher was involved in establishing the "ecological genetics" approach to studying evolution, using conspicuous color and pattern polymorphisms for detecting selection in nature, especially in Lepidoptera, in collaboration with E.B. Ford (Fisher 1953). This was paralleled by the collaboration between Wright and Theodosius Dobzhansky on studies of natural populations of *Drosophila pseudoobscura*. Both sets of investigations were important in demonstrating that natural selection can be detected on traits that might superficially seem unimportant, leading eventually to thousands of studies demonstrating the action of natural selection in wild, domestic and human populations. Fisher also made important contributions to research on human blood groups, the earliest source of biochemical genetic markers in population genetics (Fisher 1953).

This brief summary of Fisher's major contributions to evolutionary biology cannot do justice to his originality, depth of thought, and mathematical virtuosity. But it should provide some idea of how important his work has been for the development of modern evolutionary biology.

[Fission-fusion dynamics](#); [Fusion-fission](#)

## Definition

Fission-fusion is a property of many animal groups that split in temporary aggregations or subgroups. First described in hamadryas baboons (*Papio hamadryas*; Kummer 1971), it has been found in an ever-larger number of species, including elephants, hyenas, dolphins, chimpanzees, and several other primates. *Fission-fusion dynamics*, as the term is currently used, consist of the temporal variation in the spatial cohesion between group members, who form subgroups that can also vary in size and composition over time, due to splitting and coming together with other subgroups. Because different species show a different extent of temporal variation in these three dimensions (spatial cohesion, subgroup size, and subgroup composition), they can be characterized by their *degree* of fission-fusion dynamics (Aureli et al. 2008). Resulting in part from the benefits of foraging in variable environments, these dynamics are an important part of social complexity. Fission-fusion dynamics influence the opportunities for individuals to interact, introducing uncertainty about the whereabouts of other group members and the social relationships they hold with each other. As such, they are relevant for the study of the cognitive and communicative mechanisms used to deal with this social uncertainty. It is believed that early hominid societies also showed fission-fusion dynamics, as do contemporary hunter-gatherer societies and even urban populations (Rodseth et al. 1991). Thus, the study of the cognitive mechanisms underlying fission-fusion dynamics is relevant for the study of the evolution of cognitive abilities according to the social intelligence hypothesis, which posits that complex cognitive skills and large brains may be directly related to the complexity of the social realm (Humphrey 1976).

## History of the Term

In his 1971 book Hans Kummer used for the first time the term “fusion-fission” to explain the social system of some group-living primates, but the inverted order “fission-fusion” became the

standard term. This term was introduced to describe the social system of chimpanzees, geladas, and hamadryas baboons, that change the size of their groups by means of fission into and fusion of subunits (called parties or subgroups) according to their activities and the availability and distribution of resources. Different types of fission-fusion patterns can be recognized depending on their subunit (Rodseth et al. 1991). Two main types of subunit were recognized, borrowing terminology from chemistry. In “atomistic communities,” the smallest unit is the individual (like an atom) that moves from one subgroup to another, whereas in “molecular communities” the smallest unit is a stable one-male unit that may include several females (like a molecule formed by several atoms). Atomistic communities, which are typical of chimpanzees, bonobos, dolphins, and spider monkeys, were also called “fission-fusion societies.” Molecular communities are typical of elephants, geladas, hamadryas baboons, and snub-nosed monkeys and are also called “multilevel societies,” in which different grouping levels are recognized, from large night aggregations to small foraging one-male units with a fixed composition (Grueter et al. 2012).

The terminology used by Kummer (1971) also entered anthropology as it became clear that human societies also show fission-fusion patterns, having elements of the atomistic communities during the day, as it is the single individual that moves from one subgroup to another (Rodseth et al. 1991). However, at night individuals tend to return to the same fixed unit, resembling molecular communities. Later on, it was shown that species other than primates, such as elephants, dolphins, spotted hyenas, bats and parrots, also show fission-fusion patterns, each with their peculiarities (e.g., Bradbury 2003; Willis and Brigham 2004; Smith et al. 2008). Recently, the modal fission-fusion types were called into question about whether they can actually capture the pronounced variation in the fission-fusion patterns documented across and within species. Thus, a fundamental change in terminology was proposed.

Aureli et al. (2008) proposed the use of the term “fission-fusion dynamics” to refer to the

extent of variation in spatial cohesion and individual membership in subgroups over time. As a consequence, any animal social system can be characterized by its degree of fission-fusion dynamics, varying from highly cohesive with fixed membership to highly fluid with flexible membership. This perspective fits Kappeler and van Schaik’s (2002) degree of spatiotemporal cohesion as a key component of social organization. The revised concept offers the opportunity for comparative studies of socioecological factors that affect the degree of fission-fusion dynamics as a key component of social systems across species. Aureli et al.’s (2008) article generated a revival of research on fission-fusion patterns. In more than 30 years since the publication of Kummer (1971)’s book fewer than two articles on fission-fusion patterns were published each year. This changed dramatically after 2008 with a more than 10-fold increase in the yearly publication rates of such articles.

### Scientific Relevance of Fission-Fusion Dynamics

Fission-fusion dynamics are relevant to the social intelligence hypothesis, which posits that complex cognitive skills and large brains may be directly related to the complexity of the social realm (Humphrey 1976). Indeed, many of the species with high degrees of fission-fusion dynamics have a relatively large neocortex, including dolphins, elephants, and chimpanzees (Barrett et al. 2003). While the study of early hominid ancestors reveals little about their grouping patterns, a high degree of fission-fusion dynamics may have acted as a selective pressure on the evolution of human cognitive abilities, if we assume that the common ancestor of humans, bonobos, and chimpanzees shared the grouping patterns of the three existing species (Grove et al. 2012).

Fission-fusion dynamics are also relevant to foraging efficiency (Kummer 1971). High degrees of fission-fusion dynamics allow species to efficiently exploit food resources that vary in abundance and distribution, both in space and

time. One way of coping with this variability is forming flexible subgroups that can change in size according to resource availability at a given location or period in time. As a consequence of this flexibility, animals need to coordinate when spatially separated, so there is a role for long-distance vocalizations and other forms of communication that can maintain contact between highly separated group members (Ramos-Fernandez 2005).

Fission-fusion dynamics are also relevant to the study of group coordination and decision-making (Sueur et al. 2011). When deciding where to forage, for example, groups with low degrees of fission-fusion dynamics have to reach a consensus on where to go or follow a single leader. For example, during their morning departures, chacma baboons follow the adult males (Stueckle and Zinner 2008), while Tonkean macaques seem to reach a consensus on the direction where all of them will go before they initiate a collective movement (Sueur and Petit 2008). On the contrary, groups with high degrees of fission-fusion dynamics can split in subgroups when not reaching a consensus. Such is the case of colonies of Bechstein's bats, which increase their fission rates when their members have conflicting information about suitable communal roosts (Kerth et al. 2006). In spotted hyenas (*Crocuta crocuta*), an individual with high dominance rank will be found in larger subgroups and feeding at higher rates than low-ranking individuals, suggesting that low-ranking individuals avoid others more often in order to avoid feeding competition (Smith et al. 2008). Thus, in groups with high fission-fusion dynamics we find a greater flexibility in how individual behavior relates to group dynamics, as animals have the alternative to split from others in addition to simply following a leader or trying to impose a decision on the rest of the group.

## Adaptive Features

Fission implies a reduction of group size by forming smaller subgroups. If everything else stays the same, this reduction carries potential

costs and benefits. For fission-fusion dynamics to be adaptive, the potential costs need to be outweighed by the benefits.

A possible cost associated to fissioning into smaller subgroups is the increased predation pressure. While difficult to measure, this cost can be important in species in which being in a large group serves as a protection against predation, due to increased vigilance, dilution effects, or cooperative mobbing (Beauchamp 2017). Another possible cost is the reduction in strength of cooperative defense of group resources against other groups. In chimpanzees and spider monkeys, certain individuals form subgroups that patrol the group's territorial boundaries and defend it from neighboring groups, sometimes even raiding the territories of neighboring groups. The size of these subgroups may determine their success in aggressive encounters with subgroups from the neighboring group (imbalance of power: Manson and Wrangham 1991).

The main benefit of fissioning is the reduction of local resource competition. When food is scarce, individuals fission into smaller subgroups that exploit several small food patches, reducing competition with other group members. For example, during the dry season, when less food is available, spider monkeys do not increase their aggression rates, probably because they form smaller subgroups which effectively reduce competition (Asensio et al. 2008).

Fissions can also be effective in managing social conflicts (Asensio et al. 2008). Avoiding other group members who have been aggressive in the past by fissioning can be a strategy by victims of this aggression (Smith et al. 2008). Fusions, in turn, can create potential conflict. Aggressive interactions between individuals that were previously in different subgroups are higher after fusion than at other times (Aureli and Schaffner 2007).

One important consequence of adjusting subgroup size to local resource availability and thus reducing the intensity of contest competition is that dominance relationships between females (the sex whose fitness is more closely related to foraging success) are often not particularly pronounced in species with a high degree of fission-

fusion dynamics. However, potential differences in reproductive outputs across females of the same group may result by their use of areas with different quality within the group's home range (Emery Thompson et al. 2007; Asensio et al. 2015).

In general, individuals in larger groups incur in higher ranging costs than those in smaller groups living in similar environments because they need to travel farther to obtain sufficient resources for each group member. Fission-fusion dynamics deal with these ranging costs as larger subgroups occur mainly when resources are abundant. As a result, there are no differences in ranging costs between larger and smaller subgroups of spider monkeys (Asensio et al. 2009).

Another important benefit of fission-fusion dynamics in heterogenous environments is that individuals can take advantage of more foraging sites, discovering and exploiting them more effectively than a single, cohesive group would. As evidence for this, the spatial dispersion of subgroup members, as well as the rate of fission and fusion are higher in more heterogenous environments (Pinacho-Guendulain and Ramos-Fernandez 2017).

Fission-fusion dynamics have also been shown to provide effective means to deal with large-scale environmental disturbances, such as hurricanes (Schaffner et al. 2012). When two hurricanes passed through the home range of a group of Geoffroy's spider monkeys (*Ateles geoffroyi*) in the Yucatan peninsula in 2005, they left most trees without branches. As a consequence, fruit production was very poor for several months. The highly frugivorous spider monkeys reduced fusion rates and stayed in small subgroups. By doing so, they travelled less and invested more time in foraging, which was needed because their diet was mostly made of young leaves.

Different benefits of fissioning and fusing may apply to different species and to groups of the same species depending on different circumstances. Still, in each case fission-fusion dynamics allow flexible responses to environmental changes. Such flexibility can also have consequences for a species geographical distribution. For example, there is evidence that a high degree

of fission-fusion dynamics may allow spider monkeys and chimpanzees to live in habitats that would otherwise not be able to sustain them in their typically minimum viable group size (Korstjens et al. 2006).

## Mechanistic Basis

While there is evidence that the flexible adjustment of the size of subgroups to the current food availability is one of the main benefits of fission-fusion dynamics, how animals actually implement this adjustment is less well known. One possibility is that aggression over resources at the patch level simply limits the number of individuals that can feed in a given patch. Indeed, spider monkey subgroups in which aggression occurred were larger relative to the patch size than those subgroups where aggression was not observed (Symington 1988). Thus, individuals might be better off fissioning and searching for alternative patches than staying in a larger subgroup and face high rates of aggression. Whether they find an alternative patch depends on the abundance of these patches in the habitat. Fusions, on the other hand, can result from several individuals coinciding at the same foraging patch. Therefore, subgroup size and the rate of fissions and fusions may depend on food availability at the patch and habitat levels.

A simulation model aimed at uncovering some of these mechanisms (Ramos-Fernández et al. 2006) found that simulated foraging agents can coincide in preferred feeding patches, forming variable-sized subgroups, even in the absence of specific rules for social interactions. These foraging agents, who have knowledge about the location of feeding sites and their history of previous visits, would also split in smaller subgroups, while avoiding already visited patches. The largest subgroups, with the most variable composition, were found when large patches were neither too abundant nor too scarce, that is, when heterogeneity was maximal. This approach is useful for finding the minimum mechanisms that would give rise to a pattern resembling fission-fusion dynamics, in which subgroup size can be adjusted to the

availability of food in the environment (Aureli et al. 2008).

Environmental heterogeneity may also influence the flow of information about the location of foraging sources. If by virtue of splitting in different subgroups individuals gain information about different foraging sources, their decisions on whether to join others or split may be influenced by this different knowledge (Ramos-Fernández and Morales 2014). Additionally, they could be exchanging information about the location of available feeding patches by leading and following others at different times. Collectively, the group might thus have a more complete knowledge of the environment than any single individual. It is possible that, during food-limited periods, individuals decide to fission and fuse with those particular group members that have information about the location of fruiting trees.

A key feature of fission-fusion dynamics is that, by being away from other members of their own group, individuals may have fewer opportunities to interact than those in more cohesive groups. In groups with high degrees of fission-fusion dynamics as well as high levels of cooperation among group members, the differentiated and long-term social relationships must be regulated and maintained using partial information and through less frequent social interactions than in groups with lower degrees of fission-fusion dynamics. Thus, there are several mechanisms that have been hypothesized to play a role in facilitating fission-fusion dynamics, both at the behavioral and cognitive levels (Aureli et al. 2008).

At the behavioral level, interactions aimed at avoiding conflict, such as appeasement or greeting behaviors, seem to be important when group members reunite after being in different subgroups. These behaviors may reduce uncertainty and reinforce social relationships between individuals even when opportunities for interaction may be interrupted by the frequent fission in different subgroups. In spider monkeys, such greetings in the form of embraces greatly reduce post-fusion aggression (Aureli and Schaffner 2007). The use of some form of greeting between group members joining at fusion has also been

reported in other species, such as spotted hyenas and bonobos (East et al. 1993; Hohmann and Fruth 2000). Long-distance signals, such as vocalizations, or long-lasting signals, such as olfactory marks, play a relevant role in maintaining contact between closely associated group members that may nevertheless spend time in different subgroups (Janik and Slater 1998; Ramos-Fernandez 2005). The information transmitted by these signals may simply be about the signaler's identity, which receivers may interpret depending on their own relationship with the signaler. Additionally, these signals may also aid in distinguishing group members from individuals of neighboring groups.

At the cognitive level, inferential skills, like transitivity (i.e., the capacity to infer the linear order of magnitudes based on partial information), or relational concepts, like dominance hierarchies, may allow individuals in groups with high degrees of fission-fusion dynamics to keep track of their own relationships and the relationships between others and predict other group members' behavior using partial information (Aureli et al. 2008). However, simpler emotion-based mechanisms could instead play a role. For example, animals can make their behavioral decisions on the basis of the emotional states associated with each potential partner, which are affected by previous social interactions. Such an emotional bookkeeping may allow individuals to monitor each relationship they hold, albeit they have only intermittent contact with other group members (Schino and Aureli 2009). Other abilities, like inhibitory control (Amici et al. 2008), may allow individuals to suppress certain behaviors depending on the social contexts, which are always changing in groups with high degrees of fission-fusion dynamics.

## Prospect for Future Research

If we conceive fission-fusion dynamics as a property of any social system (Aureli et al. 2008), then it is necessary to develop metrics of the degree to which this property is present in any particular situation, group, or species. These metrics would

allow researchers to compare different species to test hypotheses about the evolution of social behavior and the mechanisms underlying it. Among these, the social brain or social intelligence hypothesis can be tested using quantitative metrics of the degree of fission-fusion dynamics and relating them with quantifications of the particular cognitive abilities that are supposed to be useful for dealing with the complexity of the social environment.

The temporal variation in spatial cohesion, one of the dimensions of fission-fusion dynamics, is particularly hard to measure. Not only are there practical limitations in monitoring the exact position of all group members, but it is also challenging to determine how dispersed is a given configuration, from the perspective of the animals themselves. For example, identifying significant clusters of individuals based on their interindividual distances can be challenging (Aureli et al. 2012), moreover if they are involved in a collective movement (cf. Farine et al. 2017). Ideally, these measures should take into account the fact that two individuals, even if separated by a relatively long distance, might still be in contact through visual or auditory means and therefore remain as part of the same cluster or subgroup of individuals. As telemetric data of animal movement accumulates, it will be possible to develop accurate measures of cohesion and definitions of subgroups based on each species' within-group spatial distribution.

Given the diversity of species in which high degrees of fission-fusion dynamics have been reported (Aureli et al. 2008), it is clear that such dynamics appeared multiple times in different evolutionary lineages. Investigating both the functional and mechanistic aspects of fission-fusion dynamics should therefore consider the evolutionary history, without necessarily assuming that high degrees of fission-fusion dynamics serve the same function or that the same mechanisms are in place in all lineages of interest. At the same time, comparative studies should explicitly consider the role of phylogeny when finding differences or similarities between fission-fusion dynamics and their underlying mechanisms in different taxa.

Investigating the underlying mechanisms of fission-fusion dynamics can profit from two complementary approaches: experiments and agent-based models. In the former, cognitive abilities or behavioral interactions are explored in experimental settings in order to examine expected differences between species with different degrees of fission-fusion dynamics (e.g., Amici et al. 2008). This approach is promising because it uses clear hypotheses that are rigorously tested. Modeling approaches explore the most parsimonious rules of behavior or cognitive mechanisms that could give rise to a particular grouping pattern, via simulations in which fission-fusion dynamics arises depending on the behavior of individual agents (e.g., Ramos-Fernandez et al. 2006). This approach is promising as a proof of concept that can fruitfully complement empirical results or even be used to generate hypotheses that can be tested via new observations in the study system.

Individuals living in groups with high degrees of fission-fusion dynamics clearly face a higher social uncertainty than those living in more cohesive groups with more stable membership. This uncertainty can be simply about the whereabouts of other group members, but it can also be about the current status of the social relationship individuals hold with each group member, which is updated only when they are in the same subgroup. Capturing this social uncertainty through the appropriate metrics should aid the development of hypotheses about the particular cognitive and behavioral mechanisms that have evolved to cope with the uncertainty that results from flexible social dynamics.

## Conclusions

The study of the mechanisms and adaptive properties of fission-fusion dynamics is an increasingly important field within the behavioral sciences. The ability to form variable-sized subgroups allows animals to forage in variable environments, reducing feeding competition. At the same time, this variability introduces challenges for the maintenance of social relationships, which may need to be dealt with using increasingly

sophisticated cognitive mechanisms. Because the human lineage is likely to have lived in groups with high degrees of fission-fusion dynamics for a long time, the study of fission-fusion dynamics may shed light on the origins of human social intelligence.

## Definition

*Fitness*: the change in frequencies of alternative forms of an organismal trait over time in a population. Change can be within a generation, in which case transmission to the next generation depends on genetic and nongenetic inheritance, or among generations, in which case inheritance is implicit.

## Introduction

Fitness is central to Darwin's theory of evolution by means of natural selection, and the concept of fitness is intimately tied to that of adaptation (Darwin 1859; Fischer 1930). What Darwin called the “struggle for existence,” later referred to as “survival of the fittest” by H. Spencer (1866), is the idea that the *fittest entities* in nature are those best *adapted* to prevailing environmental conditions. Fit entities are better at surviving and reproducing in given environments, spreading higher numbers of copies of their characteristics (or, rather, traits) through generations and in the population. The above highlights three important points:

1. Natural selection acts on entities that exhibit variations in traits (i.e., different forms of those traits) that can be passed on from parents to offspring. It is *heritable trait forms* (not necessarily genetic) that lead to greater overall fitness of individuals, and it is the trait forms that endure through generations and spread or decline in the population.
2. Fitness depends on the environment. A trait form can be adaptive (conferring high fitness) in a given environment but maladaptive (conferring low fitness) in another.
3. Darwinian fitness is a *relative*, frequency-based measure, that is, characteristic of a population of individuals. It is the fitness of a given trait form relative to others that matters to the individuals that carry the trait form. This is because natural selection operates in terms of changes in frequencies, not absolute numbers (Poulton 1884; Clarke 1979). Thus, the key concept of fitness for natural selection is the “fitness difference” among alternative forms of a trait (Endler 1986).

Defining and refining the concept of fitness has been an ongoing exercise in the field of evolutionary ecology (Hamilton 1964; Caswell 1980; Grafen 1982, 1984; Lucas et al. 1996; Queller 1996; McGraw and Caswell 1996; Hunt and Hodgson 2010). Here, we provide a condensed overview of the concept for graduate students, academics, and practitioners.

## Unit of Selection in Defining Fitness

Most evolutionary biologists view fitness as the property of an entity that is a biological characteristic of individuals: a genotype or group of genes (Hamilton 1964; Williams 1966; Grafen 2009). Successful genotypes under selection have high fitness and will proportionally increase at a higher rate in the population. A problem from this general viewpoint is that each genotype is unique and is diluted by inheritance, since only half of a genotype can usually be passed on to offspring. An alternative viewpoint is that selection occurs at the level of the single gene (Dawkins 1976). In

this case, the individual phenotype – and its interactions with the environment – is viewed as a competitive vehicle shaped by the gene (and its interaction with other genes), to ensure the gene’s journey through generations to immortality (Dawkins 1976, 1982). Here, fitness is theoretically measured at the level of the gene (Gardner and Welch 2011). However, this concept also appears impractical, since most phenotypic traits in real-world organisms are governed by the additive effects of an infinite number of loci distributed all over the genome, each having an infinitesimally small effect on a character (Hill and Kirkpatrick 2010). As emphasized by Mameli (2004), one issue with current views of evolution is the premise that natural selection acts on genetic variation or genetically caused variation. Yet, the modern evolutionary synthesis is currently undergoing a profound paradigm shift with growing evidence that not all forms of inheritance are genetic, and evolutionary models need to account for both sources of genetic and nongenetic inheritance in predicting evolutionary change (Helanterä and Uller 2010; Danchin et al. 2011; Danchin 2013). An example of nongenetic inheritance is maternal care behavior (licking and grooming) in rodents (Champagne 2008). Maternal care behavior is related to variation of specific (epigenetic) factors that modify the expression (not the DNA sequence) of given genes, themselves related to the expression of maternal behavior (Weaver et al. 2004; Champagne 2008). Such epigenetic trait forms may be passed on through generations with important implications for how we think about natural selection (Danchin 2013).

Because trait variation (whether anatomical, physiological, behavioral) is shaped by heritable sources of variation that are both genetic and nongenetic, fitness differences are likely best measured at the level of the phenotypic trait – integrating all sources of phenotypic variation. Empirically, this approach further provides the advantage of practicality, since measuring phenotypic characters (e.g., height) is straightforward and does not require making assumptions about the genetic and nongenetic architecture underlying trait variation. Measuring selection on traits often makes the assumption that traits are

independent with respect to change between generations, disregarding the fact that some traits coevolve or are genetically (or nongenetically) linked (Falconer 1981; Lande and Arnold 1983; Charmantier et al. 2014). However, refinements in statistical methods and computing algorithms are progressively allowing us to parse out sources of variation underlying phenotypic traits (Kruuk 2004; Kruuk and Hadfield 2007), including between correlated traits (Lane et al. 2011; Bize et al. 2017). Those models provide promising avenues for understanding the importance of genetic and nongenetic sources of variation in evolution (Charmantier et al. 2014).

### A Caveat: Inclusive Fitness

One of the most significant advances in defining Darwinian fitness came from Hamilton (1964) and his concept of inclusive fitness. First advanced by Darwin (1859), and later discussed by Fischer (1930) and Haldane (1932), Hamilton laid out the mathematics for explaining how apparently altruistic behavioral traits might evolve, i.e., traits favoring the reproduction of others at a cost of one's own reproduction and survival. Such an evolutionary strategy, termed kin selection by Maynard Smith (1964), results if the net fitness benefits of expressing cooperative or helpful traits, weighed by the degree of relatedness to the helped individual, outweigh the costs suffered by the helper. This breaks fitness into direct and indirect components, inclusive fitness being the summation of the two. An indirect component to fitness due to helping behavior comes about according to Hamilton's rule:  $rB - C > 0$ . Here,  $B$  is the fitness benefit of the cooperative behavior to the recipient,  $C$  the fitness cost of the behavior the donor, and  $r$  the degree of relatedness between the donor and recipient (not the intrinsic rate of natural increase of a population, but unfortunately given the same symbol). Inclusive fitness reduces to direct fitness when there is no helping behavior, that is, when the indirect component is zero. A similar argument can be applied to behaviors that appear spiteful: behaviors that hinder unrelated individuals more

than kin (Dobson et al. 2000; West and Gardner 2010).

### Measuring Fitness in Practice: Annual Measures

As a practical matter, fitness differences among alternative forms of a trait can only be measured from the reproductive success of the individuals that exhibit the particular trait forms. Reproduction and survival each contribute to the number of successful offspring that individuals with a particular trait form produce. Thus, if we ignore the effects of genetic (and epigenetic) architecture, the task seems fairly simple: simply add up the number of offspring that each individual produces and average individuals that exhibit each trait form. The point is to use the success of individuals relative to others to estimate the fitness of trait forms.

The simplest measure of fitness in an experiment, or in populations where individual life histories are known (e.g., annual schedules of reproduction and survival), is to consider individual annual reproductive success and individual annual survival separately as components of fitness. More comprehensively, both measures can be combined by counting the number of gene copies present in a population from 1 year to the next, for each individual in the population (Qvarnström et al. 2006). For example, this approach was used in common terns, *Sterna hirundo*, where the timing of egg laying was studied with respect to annual number of fledglings, annual survival to the next year, and a combined annual fitness measure (Dobson et al. 2017). The annual fitness measure was the number of individual gene copies surviving to the next year: for a given individual, this represented half the number of the fledglings it produced (because young carry half of each parent's genes), plus its survival to the next year (0 or 1). Perhaps the most comprehensive approach to measuring annual fitness is to consider both the combined fitness measure and concurrently break it down into its fecundity and survival components (see also Raveh et al. 2015).

## Measuring Fitness in Practice: Lifetime Measures

The drawback of annual and shorter-term fitness measures is that they do not account for effects that last longer during the lifespan. For example, an advantageous environment during an individual's developmental period can lead to improved reproduction and survival over the lifetime (for an example in bighorn sheep, *Ovis Canadensis*, see Pigeon et al. 2017). Capturing such effects requires working at the scale of an individual's lifetime. This is termed "lifetime reproductive success" or LRS, and it has been extensively applied (we know of no detailed review, but a search of the Web of Science for the term "lifetime reproductive success" brings up about 1000 articles at the time of writing). While it would be preferable to measure offspring production as those that go on to reproduce themselves, offspring production is most often measured at an earlier stage (such as eggs laid or juveniles produced), usually because of the complexity in natural history studies to tease apart whether juvenile disappearance from the population is due to emigration or death.

Lifetime reproductive success suffers from an important drawback: fitness differences depend on the timing of reproduction, not just the number of offspring. Timing is especially important for organisms with long lifespans, so that survival becomes a critical aspect of any measure of fitness (e.g., in seabirds; Jouventin and Dobson 2002; Reed et al. 2008). Reproduction cannot occur without survival to reproductive age, the number of times that an individual reproduces requires extended survival, and the rapidity of offspring production may itself influence survival patterns. For all of these reasons, two measures of fitness have been commonly used, net reproductive rate (usually symbolized as  $R_0$ ) and the intrinsic rate of population increase (symbolized as  $r$  or the related  $\lambda = e^r$ ,  $\lambda$  is called the "finite rate of population increase") (de Jong 1994). These practical measures are applied to subgroups in a population in which individuals express alternative forms of a trait.  $R_0$  is not standardized by generation time, which might differ among different trait forms.

Thus,  $r$  or  $\lambda$  are preferred fitness measures that take the timing of reproduction into account (Stearns 1992).

The usual procedure is to separate a population into groups representing alternative trait forms and then treat the groups as though they were independent populations themselves. Life tables with information on reproduction and survival are commonly used to calculate rates of population growth, assuming that vital rates will not change. A life table can also be constructed for individuals, treating each individual as a population that exhibits the trait form (for examples of individual fitness at different ages at maturity in sparrow hawks and blue tits, see McGraw and Caswell 1996). The reproductive rate is simply the reproduction for the individuals, and the survival rate is 100% throughout life. A measure of population growth such as  $\lambda$  can then be calculated from an algebraic matrix that reflects the individual's success at reproduction and survival. Individuals with different trait forms are then averaged as separate subpopulations within the larger population. The alternative trait form with the greater average  $\lambda$  value is judged to have greater fitness and thus at an advantage during natural selection.

The individual matrix approach (McGraw and Caswell 1996; Oli and Armitage 2008; Viblanc et al. 2010) uses individuals to estimate the fitness benefits of different forms of the trait and should provide a good comparison of alternative trait forms, if all individuals lived the same lifespan and were born in the same year. In real populations, however, individuals are often born at different times. This leads to a problem, because individual fitness measures will be higher when a population is growing and lower when a population is declining. Because natural selection produces changes in gene frequencies, fitness must be considered relative to what others in the population are doing. In an increasing (or decreasing) population, an individual with an individual fitness value of 1.0 is below (or above) average, and the trait forms that the individual carries will decline (or increase) in frequency. The solution to this problem is methodological: one should take changes in population size into account. This can

be done by comparing individual fitness to how the population is changing during the lifetime of the sampled individuals. For instance, in Columbian ground squirrels (*Urocitellus columbianus*), changes in population size during each individual's lifetime were used to calculate an "individual" estimate of population change over the lifespan (Viblanco et al. 2010). In an unpublished study (Dobson et al., manuscript), individual fitness was also compared to changes in population size during an individual's lifetime using a traditional "Leslie matrix" measure of population growth (after Leslie 1945; for details of methodology, see Caswell 2001). In both approaches, individual fitness estimates can then be adjusted for population growth during the individual's lifetime using regression analyses to provide an individual fitness estimate that is stripped of the influences of changes in population size.

fitness can be estimated from females that have no close kin nearby that can help them. For the indirect component, it is necessary to estimate the individual fitness of females that received help and subtract (strip) away the estimate of direct fitness, leaving the residual fitness due to the help of their relative. When this procedure was applied to ground squirrels, the direct component of fitness accounted for about 60% of a female's estimated fitness and the indirect component the other 40%. This result suggests that individual fitness was much higher when helping was present, and significant differences in the actual fitness estimates bore this out. This example shows the advantage of studying the fitness of trait forms, even when the basis of genetic variation is unknown or in question. If genetic variation in helping behavior had been present, it would have had a strong fitness advantage.

## Return to the Inclusive Fitness Concept

The above annual and lifetime practical fitness measures are suitable for traits when there is no indirect component to inclusive fitness. But if the traits influence the success of other individuals, such as close kin, then additional care is necessary. In a study of fitness effects of the presence of close kin in cooperative females of the Columbian ground squirrel, an attempt to estimate inclusive fitness and its direct and indirect components was made (Dobson et al. 2012). The specific behavioral traits were estimated from the presence or absence of female close relatives in this matrilineal species, but evidence suggested that the beneficial trait was the propensity or rate of aggressive behavior. Individual fitness measures relative to population size were calculated as described above for 70 females (after Viblanco et al. 2010).

The major difficulty for calculating direct and indirect components of individual fitness is to count each fitness component only once (Grafen 1982; Creel 1990; Lucas et al. 1996; Queller 1996). Hamilton (Hamilton 1964, well explained by Oli 2003) described a process of "stripping away" the effects of help so that they are singly counted. In practice, the direct component of

## Caveat Emptor

Fitness is a complicated topic because it applies to trait forms, but can most easily be measured from the individuals that carry the trait forms. And this is "fitting," since it is the individuals that survive and reproduce. But this means that each trait form is embedded within the other traits that the individuals exhibit. Thus, when there are interactive effects among trait forms, as is likely, current methods of measuring fitness will have to be modified. Current models of natural selection take associations and interactions among trait forms into account by examining a genetic variance-covariance matrix for the traits involved (Houle 1991; Stepan et al. 2002). Thus, in the future, the fitness of individual trait forms may have to be modeled within a matrix of organismal traits, as well as for its genetic and nongenetic components.

### Modal Action Pattern (MAP)

A fixed action pattern (FAP) is a species-specific, stereotyped behavior pattern that once triggered by an environmental stimulus continues to completion without further modification by the initial stimulus. The behavior is innate and not subject to individual learning.

The genesis of the FAP can be traced to the works of Charles Otis Whitman and Oskar Heinroth, two members of the emerging school of European ethologists, who independently proposed the concept of “species-specific units of behavior” (Lorenz 1981; Schleidt 1974). However, it was Konrad Lorenz who further developed the concept and became its most vocal advocate. The term fixed action pattern was first used as the moniker for this type of behavior in Thorpe (1951), a report published following the 1949 symposium for the Society for Experimental Biology on Animal Behaviour (Schleidt 1974). Prior to this several different terms were employed. Konrad Lorenz’s own writings illustrate the changing descriptor, as documented by Schleidt (1974). Initially, Lorenz adopted Heinroth’s term “*arteigene Triebhandlung*” (species-specific action drive), before switching to the term *Instinkthandlung* (instinctive action), then *Instinktbewegung* (instinctive movement), and finally *Erbkoordination* (hereditary coordination). When writing in English, Lorenz used the terms “innate

behavior pattern” and “fixed motor pattern” (Schleidt 1974). Lorenz’s collaborator Nikolaas Tinbergen proposed the use of the term “fixed pattern” (Tinbergen 1951, p. 87), but used the term “typical form” when describing signaling behavior (Tinbergen 1964, p. 223). This flux in terminology seems to have reflected the ongoing development of the concept by its authors, although, perhaps not surprisingly, it often caused confusion (Barlow 1977). Despite this variable terminology, the development of the FAP concept provided a framework with which ethologists could articulate the broader concept of instinctive behavior. Central to ethological thinking was the idea that many behavior patterns occurred without prior experience or learning and were therefore under the influence of genes. Such instinctive behaviors could be compared across species and lead to hypotheses about their evolution.

Following its initial inception, Lorenz (1970) and others (see Dewsbury 1978) identified several criteria/characteristics that could be used to identify a behavior as a Fixed Action Pattern. Schleidt (1974) articulated Lorenz’s development of these criteria, while Gadbois et al. (2015) provide a summary of their criteria using modern terminology. They can be summarized as follows:

1. Stereotypy: FAPs are composed of a ridged predictable sequence of components that are not altered by novel environmental conditions.
2. Species specificity: The behavior pattern is genetically determined and all individuals of the species respond the same way.
3. Spontaneity: The longer an animal has gone without performing the FAP, the more likely it is to occur in the absence of its triggering stimulus (vacuum behavior), while the more recently it has occurred the less likely it is soon to occur again.
4. Not goal-oriented: The actor is not aware of the purpose of the FAP.

Schleidt (1974) noted that Lorenz settled on these first four criteria in his later writings, with stereotypy being the most important defining criteria. Additional criteria include:

5. Stimulus specific: A FAP is typically triggered by a specific stimulus (sign stimulus), but cannot be subsequently modified by it.
6. Context specific: A FAP typically occurs within a specific context or situation. However, as noted in 3, this is not always the case.
7. Nonmodifiable: Once triggered by the appropriate stimulus, a FAP is obligatory and will continue to completion without modification by conscious or cognitive input.
8. Innate: Learning and experience do not influence the expression of the FAP. Fixed action patterns are developmentally fixed and predetermined.
9. More than a reflex: FAPs are more complex than a reflex, although they are often similar in appearance.

The criteria described above have resulted in no single accepted definition, with different authors emphasizing different characteristics when trying to define the concept of a FAP. The lack of consistency in defining the term prompted Dewsbury (1978) to analyze ten major sources of FAP definitions to determine the main defining and secondary attributes that each ascribed to the term in the hope of developing a single unambiguous definition. Unfortunately, Dewsbury concluded “the term ‘FAP’ cannot presently be used in effective scientific communications” (Dewsbury 1978, p. 311). Despite this pessimistic conclusion and a general decline in its use since the 1970s, the concept of the FAP continues to persist. Recent papers follow Lorenz’s initial criteria when defining fixed action patterns. For example, Dixon et al. (2008) define a FAP as “unlearned (innate), repetitive movements in response to external stimuli that are relatively unaffected by feedback, influenced by underlying motivation and species-specific,” while Gadbois et al. (2015, p. 3) define FAPs as “predictable, genetically predetermined and rigid sequences of behavior.” Therefore, although there may be variation in the exact criteria used in defining the term, there appears to be a consensus on what types of behavior constitute a FAP.

The classic, and most frequently cited, example of a fixed action pattern is the egg retrieval

behavior exhibited by female greylag geese in response to an egg rolling out of the nest. Lorenz and Tinbergen (1970, pp. 329–330) described the behavior as follows: “When the brooding goose sights an egg lying not too far away outside the nest-cup, the egg-rolling movement definitely does not emerge immediately as a ‘decisive’ action. Instead, the goose – on first sighting the stimulus-transmitting object – briefly gazes at the egg and then looks away. When the goose’s gaze returns to the egg, it is fixated for a longer interval, and it is possible that a mild movement of the head towards the egg may be performed at this stage. After a brief series of intention movements of rapidly-increasing intensity, but of highly-variable length, the goose will stretch its neck towards the egg lying in front of its head, without moving the rest of its body. The goose frequently remains squatting in this position for a number of seconds, ‘as if spell-bound’, until rising slowly and hesitantly from the nest (without altering the posture of the head and neck) and walking towards the egg with a particularly careful gait characteristic of all locomotion in the neighbourhood of the nest-cup. . . . When the goose has approached the egg sufficiently, the egg is first touched with the tip of the beak at the point on its surface nearest the goose. . . . The lower side of the beak is then passed slowly forward over the upper surface of the egg, maintaining continuous contact, until it has extended beyond the egg and approaches the substrate on the side furthest from the goose. At this point, the bird’s entire body is seized with a peculiar tension; the neck becomes taut and the head begins to quiver quite noticeably, this delicate quivering motion persists while the egg is slowly pushed or rolled towards the goose and into the nest-cup by means of a movement of the lower side of the beak accompanied by a strangely stiff and awkward-looking curved posture of the neck. The egg finally arrives on the goose’s toes, and if it has by then passed the highest point of the nest wall it will roll into the nest-cup to join the other eggs.”

Lorenz and Tinbergen (1970) were careful to distinguish this FAP from the accompanying lateral movements of the head, neck, and beak which

allowed the goose to guide the egg back to the desired position following deviations to either the left or right. They regarded these movements as the products of a taxis. This distinction between the FAP and the accompanying taxis (orientation) movements was reiterated by Tinbergen (1951, p. 87). The distinction is important in that the FAP was considered stereotyped and independent of the triggering stimulus, while the taxis movements of the behavior pattern could be further modified by the triggering stimulus and therefore variable in their expression.

One of the driving motivations behind the development of the FAP concept was the desire, by ethologists, to understand how behavior evolved. Anatomical structures, which are discrete and readily quantifiable, had been the focus of comparative and evolutionary studies since Darwin's monumental work *On the Origin of Species* (Darwin 1859). Behavioral studies lagged behind those on morphology (although Darwin 1872 himself used the comparative method in his book *The Expression of the Emotions in Man and Animals*) with respect to the comparative method. The formulation of the fixed action pattern provided a discrete unit of behavior that could be analyzed using the comparative and phylogenetic methods applied to anatomy. In 1939 Konrad Lorenz articulated his thoughts on behavioral elements as taxonomic characteristics (Lorenz 1957) and produced, in 1941, one of the earliest phylogenetic studies using behavioral units when he analyzed the courtship displays of the Anatinae (Lorenz 1971). Later, Baerends (1958) discussed the application of comparative methods to studying the evolution of behavior, with special emphasis on identifying behavioral homology. The use of the comparative and phylogenetic analysis in animal behavior has continued to develop, although use of the classical concept of a FAP has diminished (e.g., Martins 1996).

The concept of the fixed action pattern as a definable unit of behavior found initial support from European ethologists. However, mounting criticism of the concept followed from both the comparative psychology and ethological schools of animal behavior. The focus of much of this

criticism was on the ideas that FAPs were highly stereotyped and completely innate units of behavior.

Lorenz's emphasis on the stereotypy of FAPs was questioned by a number of ethologists (e.g., Barlow 1968; Schleidt 1974). Schleidt (1974), although supportive of the FAP concept, discussed the degree of variability of FAPs and proposed methods to quantify it statistically. In concluding his paper on "How 'fixed' is the fixed action pattern," he states (Schleidt 1974, p. 207) "the adjective 'fixed' in the term FAP refers to a superficial rather than a fundamental property of such behavioral units, even if we refer to fixed as being relative, i.e., meaning 'highly' stereotyped or having low degree of variability. . . . My hope is that the acronym FAP will persist and its actual meaning will be gradually forgotten so that this abbreviation will change its meaning with the changes in the concept." The latter part of this statement was in response to the term Modal Action Pattern (MAP) that had previously been suggested by Barlow (1968). Barlow (1968) had also evaluated the concept of FAPs as a fundamental unit of behavior and concluded that most FAPs had some degree of variability and were not rigidly stereotyped. He therefore suggested fixed be removed from the term and replaced with modal. The term "modal" explicitly recognized that variation within a behavior pattern will cluster around a mode. In a subsequent paper, Barlow (1977, p. 99) provided the following definition of a MAP: "(1) A Modal Action Pattern is a recognizable spatiotemporal pattern of movement that can therefore be named and characterized statistically. (2) It usually cannot be further subdivided into entirely independently occurring subunits, although some of its components may occur independently or in other MAPs. (3) It is widely distributed in similar form throughout an interbreeding population." He then provided a guide to recognizing and analyzing MAPs before applying the concept to communication (Barlow 1977).

The use of the term "innate" was criticized by both comparative psychologists (e.g., Lehrman 1953) and some ethologists (e.g., Jenson 1961). Lehrman (1953) was one of the most vocal critics of this concept and argued against the

idea that behavior patterns could be defined as being innate or instinctive. His main point was that learning could not be ruled out when examining behavior because it is not possible to determine if learning does not occur during development in utero or within the egg. While acknowledging that “learning processes” can take place in the egg or uterus, Lorenz (1965) responded to Lehrman and other critics of the use of innateness by arguing that it was not possible to learn a behavior response for one environment while developing within another environment (the egg or uterus), that the ability to learn is itself an evolved feature and that behavior is a function of “(a) the adaptive process of evolution and (b) by individual acquisition of information” (pp. 18–19), and that neither component should be dropped from consideration when trying to understand the origins of a behavior.

As the field of ethology developed, the what some might consider simplistic concept of FAP was superseded by other more complex concepts of behavioral systems. For example, Fentress and colleagues proposed that behavior be studied in terms of “action sequences” that are determined by a system of rules and can be described probabilistically (Fentress and Gadbois 2001; Gadbois et al. 2015). However, they do not dismiss FAPs as nonexistent but recognize them as a discrete type of behavior unit that may occur (Gadbois et al. 2015). Others have made use of the highly stereotypic nature of FAPs to study their underlying control. Recently a series of papers (D. H. Kim et al. 2015; Y. J. Kim et al. 2006) have studied the role of ecdysis-triggering hormones (ETH) and peptidergic ETH receptor neuron ensembles in the central nervous system on the ecdysis FAP of pupal *Drosophila*. Through genetic manipulation of these neurons, they demonstrated that they were under the direct influence of ETH and determined the timing of behavioral steps in the ecdysis FAP sequence. These studies begin to provide insight into the mechanistic neural control of FAPs, what Lorenz and Tinbergen (1970) referred to as the *innate releasing mechanism*. Although the FAP has been marginalized to a historic footnote, these recent studies suggest that the concept continues to have relevance.

## Floor and Ceiling Effects

Jorge A. Quillfeldt

Psychobiology and Neurocomputing Lab (LPBNC), Department of Biophysics, I.B., Neurosciences Graduate Program, ICBS, Federal University of Rio Grande do Sul (UFRGS), Porto Alegre, RS, Brazil

Every time an experimental design is proposed, several pragmatic constraints (i.e., fixed variables) are decided and implemented at the same time. When dealing with new problems in a research area, where most of the results are uncharted territory, some of these fixed variables may pass unnoticed at first. Thus, good control groups are not always trivial to be defined.

When analyzing experimental data, *spurious effects* may supervene, affecting the quality of the conclusions (Cohen 1995). In psychobiology experimentation, three common spurious effects are Ceiling, Floor, and Order Effects. Order Effects – when performance depends on the order of presentation of the task components – should be easy to detect and avoid, but the same is not always true about ceiling and floor effects.

A *Ceiling Effect* takes place every time many experimental subjects reach the maximum performance allowed for the measured variable of choice. If most of the subjects in both control and experimental groups reach this score, it may be impossible to detect significant differences between them, and the experimental setup should be considered unfit to decide if the hypothesis under scrutiny is true or false. Notwithstanding this particularly bad experimental setup, sometimes it is necessary to allow some (or even most) tested subjects to reach the maximum level in order to observe certain expected outcomes (see below). Thus, while Ceiling Effects may plague poorly designed tests, they may be tolerated and managed in situations where a practical upper limit of whatever property being quantified (e.g., time to perform something) must be imposed (in this case: session duration). The same situation may happen on the other extreme of the

**Floor and Ceiling Effects, Table 1** summarizes the main aspects of ceiling and floor effects

|                                      | Ceiling Effect          | Floor Effect                 |
|--------------------------------------|-------------------------|------------------------------|
| <i>Basic characteristic</i>          | Test is too <i>easy</i> | Test is too <i>difficult</i> |
| <i>Control and. treated subjects</i> | <i>Excel</i> alike      | <i>Fail</i> alike            |
| <i>Increased risk of</i>             | False negatives         | False positives              |

performance scale, when a minimum value is obtained by all groups: this is called *Floor Effect*, the siamese twin of the Ceiling Effect (which is sometimes called *Basal* or even *Basement Effect*).

It is easier to grab these concepts in the context of human psychological tests, may them be employed for scientific or applied (clinical) purposes: Ceiling Effects take place when the task is not challenging enough (say, too easy), and most outcomes reach the maximum defined level. This sample of subjects would neither lead to a conclusion about the general trend in a population, nor allow the gauging of one specific individual. Floor Effects are just the opposite, usually appearing when the test is too difficult for the experimental subjects. Extreme scores, either above the higher (ceiling) or below the lower (floor) level, also increase the risk of, respectively, false negatives, or false positives (Banks 2011a; Page 2017). Table 1 describes floor and ceiling effects.

Ceiling (or Floor) Effects may be circumvented by a better, revised experimental design, frequently with an adequate adjustment of the controlled variables. The following example, taken from the behavioral pharmacology of memory research should illustrate these possibilities in an animal model. There are two versions of the Inhibitory Avoidance task (IA), step-down IA or step-through IA (sometimes both are inaccurately named “passive avoidance” – Netto and Izquierdo 1985). In the Step-down IA task, for instance, training sessions are typically very short (seconds to 1 min mostly), ending when the animal climbs down the platform and receives the shock (for more details, see Quillfeldt 2016). When testing aversive memory with this task, if the stimulus – a foot shock in the grid floor – is too intense, most or all animals will never step down the platform during the test session. They tend to “remember” so well the experience that has

reached a maximum response under those experimental conditions. Notice that the *duration* of the test session will be decisive to define the results: moderate shocks applied during IA training imply that a 3–5 min test session would be more than enough, and no better results would come out from a longer session. However, since the avoidance time is proportional to the shock intensity, in an experiment with a stronger shock we *might observe a different response* if the test session is extended till, say, 10 min. The arbitrary decision of imposing a smaller time, e.g., 5 min, for the session would simply render the alternative, opposite response undetectable (a false negative): it might or might not be there, we will never know. But there are other aspects to be considered, since too long test sessions would both put an unnecessary burden upon the experimental animals and consume lab time and resources: the decision rests on the two aspects, choosing the shock intensity and setting test session duration.

When there is no way to avoid certain practical constraints upon the experimental variables, important methodological consequences rise, in particular, regarding possible statistical models. In the above example, since *time* is both the measured (step-down latency) and the constrained variable (session duration) – and a test session ceiling time of 180 or 300 s is assumed – the random distribution of animal performances would hardly conform to a Gaussian curve, and data *should not be analyzed* by Parametric Statistics due to the risk of reaching false conclusions. Non-parametric tests should be used instead, and results should be presented as median [interquartile range] (a clear example of this: Izquierdo et al. 1997).

It is widely known that if a parametric test can be applied, more statistical *power* will be available, but this is valid (and reliable) *only if at least two* strong assumptions are met: (1) Normality of

data distribution, and (2) homoscedasticity (same variances in all groups). Parametric statistical tools may be richer and simpler to use (and beware of fancy software packages literally offering a *buffet* of statistical tests!), but they are also more demanding in terms of needed conditions. Ignoring that increases the chance of failure. Actually, statistical *power* should never be confused with statistical *robustness*, i.e., the capacity to resist to errors in analysis that result from deviation from (necessary) assumptions (Huber 2009). Non-Parametric statistics does not make assumptions related to any specific statistical distribution, being really more robust as a procedure. Depending on the characteristics of the data obtained, it may be the only reliable approach.

One simple way to avoid facing this annoying analytical limitation (and not appeal to data transformation) would be, in the example above, simply reduce the shock intensity to a level at which all animals will perform under the cut-off time of, say, 180 (or 300) secs. Now the collected data may conform to a normal curve, possibly displaying equal variances per group, and parametric analysis may not be so risky (see an example of this in Quillfeldt et al. 1994). Yet, a note of caution: since behavioral pharmacology usually employs a few animals per group to keep their size “as low as reasonably viable” – studies rarely use more than 15 animals/group – sample data, according to the Central Limit Theorem, would barely fit a Normal Distribution out of pure chance (Zar 1998). Considering that behavioral research employs experimental animals, the number of animals used must be kept to a minimum in order to ensure animal welfare compliance (not to mention keep costs reduced). This is why, even if data *appears to be normally distributed*, it is always necessary to check for the two assumptions, normality (e.g., employing Kolmogorov-Smirnoff or Shapiro-Wilke tests) and homoscedasticity (e.g., using Levene test for equality of variances), before jumping into parametric analysis.

Thus, as a general rule, *Ceiling Effects* usually take place in tasks that are *too easy for the subject*, i.e., when the amount of information required to process is low. Conversely, Floor effects appear with difficult tasks. In animal models, it is easier

to observe Ceiling Effects in aversive tasks such as IA (above), but they may also be present in other behavioral tasks, even nonaversive/spatial ones (Buccafusco 2001; Levin and Buccafusco 2006). Some examples: Fear-Potentiated Startle (FPS), in which setting baseline startle responses too high may result in hardly detecting differences in the following test sessions; Delayed matching-to-sample (DMTS), in which defining the retention intervals must be based on the baseline performance (accuracy) of the same subject in order to avoid a Ceiling Effect in the case of the proficient ones; Radial Arm Maze (RAM) – that may be used to study either working or reference memory – can be made more difficult in different ways, e.g., more arms being presented, longer-time delays between training and retention tests, and the complexity of the sequences of arm choices. On the other side, Contextual Fear Conditioning (CFC), another popular aversive behavioral task, compared to IA has no explicit constraints upon time because healthy animals rarely display freezing during 100% of the duration of the test session: for this variable at least, parametric statistics could be used without risk (see, e.g., De Oliveira Alvares et al. 2010).

Finally, notice that Ceiling Effects are a problem only when the variable you choose to measure is expected to *increase* its value after some interference or treatment (e.g., pharmacological or behavioral) compared to the control group, being less critical in the opposite situation, unless the effect size obtained is too small. For experimental designs in which you expect the measured variable to *decrease* compared to controls, Floor Effect may be the main problem. Obviously, when measuring more than one variable in the same experiment, there may be the case that one is plagued by these effects while the other (s) don't: thus their data can still be useful, provided the clean variable is shown to be independent from the limited one.

## Florence Merriam

Emily N. Shelton  
Averett University, Danville, VA, USA

## Synonyms

[Florence Merriam Bailey](#)

## Definition

Florence Merriam was an ornithologist and naturalist.

## Introduction

Florence Merriam was a pioneering woman in science who built a career on her passion for birds and her desire to end the practice of wearing deceased birds or bird feathers as fashion accessories. She is celebrated for the accessibility of her works for people both within and outside of academia, and her legacy is one of inspiring people to embrace nature, rather than seeking to become masters over it.

## Her Life

Florence Augusta Merriam was born on August 18, 1863, in Locust Grove, New York (Oehser 1952). Her father, Clinton Merriam, was a businessman who later served two terms as a Republican Congressman, and her mother, Caroline Hart, was a graduate of Rutgers College (Kofalk 1997). Merriam was the youngest of four children. She had two older brothers – Charles and Clinton Hart, who was referred to as C. Hart or simply Hart – and an older sister, Gertrude, who died one day before Merriam’s birth (Kofalk 1997; Tayebi 2008).

Merriam’s innate interest in naturalism and science was impacted by her family members. Her mother inspired and encouraged her

relationship with nature through her own passion for astronomy, exposing her daughter to scientific pursuits at an early age (Kofalk 1997). Her paternal aunt was a botanist who maintained an herbarium and spent time studying and collecting samples of local plants (Tayebi 2008). Clinton, Merriam's father, was a friend of well-known naturalist John Muir and was himself interested in natural history, but it was his stories about hearing the birdsong of robins at his parents' farm that inspired Merriam's love of birds and her later career (Kofalk 1997; Oehser 1952; Tayebi 2008). Merriam was extraordinarily close to her brother Hart, who remained one of her dearest friends throughout their lives, and it was his interest in taxidermy and collection of animal specimens that further inspired Merriam's love of nature while simultaneously revealing her preference for observing and studying live animals (Kofalk 1997).

Because of her relatively fragile health and struggle with what is believed to have been tuberculosis, much of Merriam's education took place at home, during which time her interest in naturalism continued to be cultivated through long walks in the forest with her father and Hart (Kofalk 1997; Tayebi 2008). After brief periods of attending public schools, including a preparatory school in Utica, New York, Merriam was permitted to study at Smith College in Massachusetts under the condition that she did so as a nondegree student who would receive no formal degree upon the completion of her education in 1886 (Kofalk 1997; Oehser 1952). Despite her successes, Merriam remained without a degree until 1921, when Smith College officially awarded her a Bachelor of Arts degree, followed by a Legum Doctor degree given to her by the University of New Mexico in 1933 (Kofalk 1997).

As an adult, Merriam's beloved brother Hart relocated to Washington, D.C., where he became the head of the United States Biological Survey – the nation's first federal program focused on natural sciences as a field (Kofalk 1997). Hart's assistant, Vernon Bailey, maintained a friendship with Merriam for nearly a decade before they were married on December 16, 1899 (Kofalk 1997). Bailey went on to become the US

Biological Survey's foremost field naturalist – a position he occupied for over 40 years that afforded he and Merriam an opportunity to travel and conduct the fieldwork that would characterize their respective careers (Kofalk 1997). While Merriam and Bailey never had children of their own, they enjoyed close relationships with their nieces and nephews and remained faithfully married (Kofalk 1997).

Bailey and Hart both died in 1942 and, having lost the two people she loved the most within such a short period of time, Merriam retired afterward to the home she had shared with her husband in Washington, D.C., where she remained until her death in 1948 (Kofalk 1997).

## Her Work

Throughout her life, Merriam's focus was on birds and ornithology. Even while matriculating at Smith College, Merriam continued to conduct ornithological fieldwork and wrote journal articles on the subject (Oehser 1952). After marrying Bailey, the couple spent the majority of their life together traveling across the United States conducting fieldwork, which was their mutual specialty, though Bailey and Merriam focused on mammals and birds, respectively (Kofalk 1997). Like many women of her day, Merriam capitalized on the freedom to travel, taking to wagons and horseback to explore the areas where trains could not take her during her explorations alongside Bailey (Kofalk 1997).

During her final year of study at Smith College, Merriam was made aware that George Bird Grinnell was founding an Audubon Society (Kofalk 1997). She set out to raise awareness and gain members, which she did so successfully that shortly thereafter, nearly one third of the college's student body had become involved, earning her a position as one of the chapter's founding members (Kofalk 1997; Oehser 1952). Though this initial chapter later dissolved, it was reborn in Massachusetts and resulted in the National Audubon Society that exists today (Kofalk 1997). Additionally, in 1885, Merriam became the first woman to be made an associate

member of the American Ornithologists' Union (AOU), which was founded in part by her brother, Hart (Kofalk 1997; Oehser 1952). She went on to become the AOU's first woman fellow in 1929 and the first woman recipient of the AOU's Brewster Medal in 1932, as a result of her rise to prominence following the release of *Birds of New Mexico* (Kofalk 1997).

Over the course of her career, Merriam wrote nearly a dozen books and over 100 journal articles (Tayebi 2008). Despite traveling and conducting fieldwork alongside one another for decades, Merriam and Bailey collaborated on only two books, preferring to keep their work separate from one another's (Kofalk 1997). The articles Merriam wrote as a student at Smith College appeared in such publications as "Audubon Magazine," and they were later compiled into her first book, *Birds Through an Opera Glass*, in 1889, which provided means of recognizing different avian species while also detailing many of her bird-watching experiences (Oehser 1952; Tayebi 2008). Her most significant work *Birds of New Mexico* consisted of over 800 pages and was published in 1928, earning her attention and acknowledgments from the AOU, as it was the first comprehensive account of avian life in that region of the United States (Kofalk 1997; Oehser 1952). For these reasons, it is widely considered to be her *magnum opus*. Her book *Birds of Village and Field* was published in 1898, and it is regarded as the first popular bird-guide book in America, with its noteworthiness being partially due to the illustrations by celebrated artists such as Louis Agassiz Fuertes contained therein (Oehser 1952). Alongside Bailey, Merriam continued to write ornithological articles which were published by notable mediums such as *The Auk* and *The Condor* (Oehser 1952). In 1902, her *Handbook of Birds of the Western United States*, which contained several hundred illustrations by Louis Agassiz Fuertes, was released; it was the first of her works to feature technical, scientific terminology and detailed descriptions of the appearances, reproduction, and behavior of various avian species (Oehser 1952; Tayebi 2008). Merriam continued to work and write into late adulthood, and her final significant work,

"Among the Birds in the Grand Canyon National Park," was released in 1939, when she was 76-years-old (Oehser 1952).

Unlike other women in her day, Florence Merriam always published her works under her own name, and it is this independence that, when coupled with her impressive career, affords her a place as one of the most prominent women naturalists and writers of the nineteenth century (Kofalk 1997). Her writings are likewise unique because they are written more for laypeople than academics or scientists, which showcases her desire to educate people about the birds and the natural world around them, as she believed that possessing such awareness and knowledge was key to protecting and celebrating nature as it deserves (Kofalk 1997). Merriam possessed the necessary knowledge and technical vocabulary to write for fellow ornithologists, but her passion was such that she chose instead to focus on lay readers, who might be inspired to go outdoors, view nature differently than they did before encountering her works, and discover for themselves the wonders that had eluded them previously (Kofalk 1997).

Decades later, her legacy lives on; she is still considered one of the most prominent sources of information on avian behavior (Oehser 1952).

## Introduction

Developmental stability is referred to as an “ideal” form of an organism to respond against random perturbations during development under a set of conditions (Palmer and Strobeck 1986). As such, abrupt deviations from the ideal condition, when stability in development is disturbed, produce a range of forms that depart from normal phenotypes. Under normal conditions, those outcomes of stability are widely known in bilateral organisms. Even though bilaterally symmetrical

organisms have been extensively used as a calibration point to assess deviations from the norm, these organisms also present developmental instability (DI), especially between the left and right sides of certain characters, and thus they have been of interest to evolutionary biologists.

Developmental instability (DI), also known as developmental noise, or treated as an outcome of that, implies subtle deviations from symmetry, which usually exhibit one of three types: fluctuating asymmetry (FA, imprecisely determined path during development); directional asymmetry (DA, general tendency in which one side shows greater development); and antisymmetry (AS, equal frequency of variation) (Fig. 1). These terms refer to patterns of variation in a particular characteristic displayed by a sample of individuals. Fluctuating asymmetry is the most studied and has become a measure of DI, especially because it is the easiest to visualize in populations due to differences in the left-right sides (L-R). However, it is a matter of debate which stressors trigger DI during ontogeny and whether genetics alone, or together with the environment, play a role in producing such variation in chirality. Despite extensive efforts to discover the development basis of FA, the underlying causes of heterogeneity are still unclear. Here, we will highlight the current state of knowledge on FA, measurements, and its applications in evolutionary biology.

## The Definition of FA

Fluctuating asymmetry is characterized by small, random departures from the symmetrical form in bilateral organisms. During DI, individuals are unable to overcome extrinsic (e.g., habitat fragmentation, thermal noise) and intrinsic (e.g., inbreeding depression, bottleneck event) stressors, exhibiting nonidentical forms on both sides of a given trait. Because phenotypes are not identical within populations, as FA implies imprecise pathways during development, FA can be used as a measure of developmental (in)stability, estimating the sensitivity of development from genetic and environmental stresses. Therefore, FA has been the subject of a lot of attention for

# Fluctuating Asymmetry (FA), Fig. 1

Three most common potential distributions of the right-left means in bilateral organisms. Fluctuating asymmetry in a population exhibits a normal distribution of the difference between the sides with a mean of zero ( $R-L = 0$ )

F

generating valuable outcomes for assessing the biological effect of stress at the population level and its impacts on fitness and heritability (see Van Dongen 2006; Benítez et al. 2020).

The search for features notably under FA is quite simple: these traits will be asymmetrical on the right-left sides and can be measured separately, considering the right-minus-left in each individual in a population (Fig. 2). These measures reflect the usual normal distribution with a mean around zero, characterized by a leptokurtic (i.e., when the distribution has an excess of kurtosis, with tails larger than the normal distribution) curve in FA. Although it is well-known to affect the behavior of populations, particularly sexual behavior, and have genetic bases still to be discovered, FA does not have adaptive biases. Basically, this claim is underpinned by the idea that symmetrical traits are the ideal form and, thus, highly genetically controlled (Tomkins and Kotiaho 2002).

## Measuring FA

Fluctuating asymmetry can be achieved as simply as measuring the size of a given bilateral trait in

the left-right sides and assigning the difference between the absolute value of both afterwards, although other indices can also be used to assess this variation (e.g., morphometrics; see Palmer and Strobeck 2003). Therefore, more symmetrical traits are those whose difference is closer to zero. However, quantifying FA among individuals can be a troublesome task, as the magnitude of FA is usually the same as the measurement error (Palmer and Strobeck 1986). Measurement error reinforces variance in a sample, especially in mean absolute deviations, which often generate apocryphal associations (Graham et al. 2010). To avoid spurious information, a statistical analysis must be included in FA observations, and the most widely used is the mixed model analysis of variance (ANOVA).

In this regard, most experts have repeatedly measured the same character on both sides to ensure accuracy in their analysis, also applied to estimate the extent of the variation during counting the focal character, which accounts for measurement error. These measurements must be taken under the same conditions (e.g., stereomicroscopy), guaranteeing the same manipulation in achieving the measures. Repeatability is of

**Fluctuating Asymmetry**

**(FA), Fig. 2** Hypothetical scheme of a *Drosophila* showing R-L wing size variation: (a) right wing size variation; (b) symmetric form; (c) left wing size variation. In fluctuating asymmetry, it is expected that small deviations from symmetry in a sample of individuals should have a larger or smaller right side (a, positive asymmetry) or should have a larger or smaller left side (b, negative asymmetry). Measurements can be taken using morphometry methods (e.g., wing width versus wing height) to estimate the fluctuating asymmetry of a population by the average of the absolute differences between both sides

paramount importance in every trait that will be analyzed, mostly because it is the principal input for the statistical analysis for both measurement error (ME) and traits (ANOVA), which will indicate if the observed asymmetry is significantly different from ME and whether it reaches a normal distribution (Graham et al. 2010). A thorough statistical procedure is available and detailed in Palmer and Strobeck (2003).

Regarding the accuracy of FA as an estimator of DI, estimated DI is rather difficult to generalize to a population, especially because FA is usually measured from two sides of a given bilateral trait

(i.e., with one degree of freedom), which reflects the DI of that individual (Leamy and Klingenberg 2005), and not the whole population, resulting in low precision as an estimator of DI variability. Therefore, to have confidence that differences in L-R sides in a population are due to FA, sampling variation should rely on many FA values. For this, FA and DI should be standardized by *hypothetical repeatability* (HR), an estimator that correlates how much of the difference observed by FA corresponds to differences in DI (Van Dongen 1998). However, even when estimating HR for a huge number of traits and values of FA, it is difficult to

establish that high values of HR express high DI, mainly because different traits may be upon different selective pressures on its symmetry. Therefore, there is a common observation of low values of HR, stressing the difficulty in estimating the degree of DI in a trait.

### More Common Than It Seems: The Evolutionary Significance of FA

Fluctuating asymmetry has been correlated with a number of evolutionarily relevant issues, such as sexual selection, mate choice, fitness, and heritability (Carter and Houle 2011; Ishihara and Miyatake 2020; Leung and Forbes 1996; Møller and Pomiankowski 1993). Most of these studies focus the attention on a particular aspect of FA at the population level, a feature that can be inferred by the degree of FA. In terms of sexual selection, for example, researchers have raised the idea that FA is a possible indicator of individual quality, a consequence of FA that directly affects individuals' behavior in natural populations. For instance, males with secondary sexual ornaments may be negatively affected by FA, as asymmetrical males indicate to potential mates that they are unable to cope with environmental stress during development, reflecting male quality (Møller and Zamora-Muñoz 1997). As such, females may benefit from choosing symmetrical males according to the “good gene” model of sexual selection.

Individual quality, especially in males, is thought to be sensitive to FA under the assumptions of three main hypotheses: (i) secondary sexual ornaments are costly to produce; therefore they are more sensitive, suffering more from environmental stress, decoupled from other highly costed, and more functional important, symmetric traits; (ii) selected traits are dependent on their expression, and the tiniest modification in that pathway triggers phenotypic deviations; (iii) symmetry is repeatedly observed in characters with a selective advantage, which makes it tempting to assume a genetic component underlying this pattern. Along with these, asymmetry in secondary sexual traits may be under recent directional selection (Møller and Swaddle 1997).

Convincing studies have demonstrated that females are biased toward choosing symmetrical males as mates, which raises the idea that females may have strengthened sensorial biases according to sexual selection models (i.e., sensory bias model). There is growing evidence that female mate choice shapes sexual selection, with empirical demonstration in birds, insects, and spiders. In insects, fireflies display a unique, and widespread, range of variation in both the left-right antennae, with cases up to 80% of asymmetry in a population (Nunes et al. 2020). Complex mate finding (i.e., using chemical components or light signals) may maintain unusual variation among taxa, which may benefit them from having extra antennomeres (i.e., more antennal surface). Another example is also reported in cerambycid beetles *Stenurella melanura* (Linnaeus 1758) in which males with symmetrical antennae were chosen more often than asymmetrical ones, reflecting that this trait has been sexually selected. However, these asymmetries characterized a sharp asymmetry between mated and unmated males, instead of slight deviations from the ideal form – which is a common form of FA (Møller and Zamora-Muñoz 1997).

Studies using tetrapods as a model system consistently show results in FA mean values among more functionally important traits in anurans and turtles (Didde and Rivera 2019; Rivera and Neely 2020). These findings agree with a growing current of thought that more useful and biologically important morphological traits may display lower degrees of FA. Especially in vertebrates, large differences in FA in limbs may decrease the performance of terrestrial animals (Trivers et al. 2013) and aerial organisms (Swaddle 1997), as well as aquatic tetrapods (Rivera and Neely 2020). This handful of examples highlight that different FA plays a different role and has evolved at different rates, according to the trait.

### What Is the Role of Environment and Genetics in FA?

An organism's development is constantly under epigenetic phenomena (i.e., molecular alterations that occur on DNA but not within DNA

sequencing, producing heritable phenotype changes), being subject to huge intrinsic perturbations. These perturbations give rise to the opportunity for unpredicted phenotypes, culminating in nondirectional departures of paired structures for perfect symmetry (i.e., fluctuating asymmetry). Environmental and genetic factors are the main drivers of FA, and their roles have been investigated in depth (Leamy and Klingenberg 2005; Mabrouk et al. 2020; Sandner 2020). Published evidence seeking signatures of both stressors upon individual development showed that FA arises whenever the environment presents higher concentrations of distinct contaminant exposure. In aquatic environments, ecotoxicological monitoring of several species of anurans and fish suggests that developmental instability increases as a result of exposure to pollutants (Seixas et al. 2016; Guo et al. 2017). As such, higher levels of FA are often found in these environments. These patterns also point to the importance of conservation policy, given that high rates of FA are found with chronic exposure to a range of pollutants, from metals to chemical components. Furthermore, these parameters are closely related to individual and environmental quality – polluted environments and higher levels of FA are suitable and reliable biomarkers for ecotoxicological studies, conservation, and prediction of FA (Leary and Allendorf 1989).

On the other hand, the role of genetics in shaping FA is still unclear and contentious. Some studies have found heritability in morphological characters (Carter and Houle 2011) while others have found no such relationship (Kruuk et al. 2003). In order to search for the role of genetics in developmental instability, researchers have focused on candidate genes (Batterham et al. 1996) and quantitative trait loci (Leamy et al. 1997, 1998). However, a consensus on whether the genetic architecture is conditional to certain characters to ensure symmetry in organisms' development awaits further investigation.

More generally, a better understanding on how the genetic pool affects the degree of FA under environmental stressors and the extent of phenotypic variation among populations is elusive. Heritable variation of FA has been reported for

artificial selection of outbred populations in the fruit fly *Drosophila melanogaster* (Meigen 1830) (Carter and Houle 2011), although natural selection has not fixed all the extant phenotypes found during artificial selection. Noteworthy, according to these findings, natural selection tends to decrease levels of FA in evolutionarily relevant traits in all wild populations, such as locomotor appendages (e.g., legs, limbs, and wings). Therefore, it is assumed that FA (and DI) is deleterious to fitness.

## Summary

Fluctuating asymmetry plays a pivotal role in mate choice, sexual selection, heritability, and conservation. To date, a broadly available literature portrays the importance of environment and genetics as a trigger of developmental instability, thus leading to higher degrees of FA in bilateral organisms. However, the mechanisms underlying FA remain to be investigated.

## Focal Animal Sampling

Mariane Bosholn and Marina Anciães  
Evolutionary Biology and Animal Behavior Lab,  
National Institute of Amazon Research (INPA),  
Manaus, Amazonas, Brazil

## Synonyms

[Focal sampling](#); [Focal sampling methods](#); [Focal observation](#)

## What is animal focal sampling?

Focal animal sampling is a method commonly used in the study of animal behavior, such as for the elaboration of ethograms (Altman, 1974). According to Altman (1974), observers using this method should sample the behaviors of only

one individual at a time, regardless of the number of individuals that could be sight during sampling. When using focal animal sampling, individuals are observed for a period of time each, recording their behaviors in intervals of pre-established duration. This method allows a more detailed behavioral sampling if compared to other sampling methods. Despite its usual application to one individual at a time, adaptations of the method to sample groups of few individuals spatially restricted have been reported (Anciães and Prum 2008; Bosholn et al. 2016).

Ideally, before beginning observations, the observers should define the recording rules. Three recording rules can be used for record behavior in focal animal sampling: continuous recording (all occurrences in the interval), instantaneous sampling (occurrences in the beginning of the interval), and one-zero sampling (first occurrence in the interval) (Martin and Bateson 1986). Subsequently, it is important to determine the duration of the time interval in which the focal individual will be observed (Altmann 1974). Observation interval duration depends on multiple factors (Altmann 1974), including characteristics intrinsic of the focal species such as mobility and habit. For species that are very active or highly mobile, such as birds, a short observation interval can be efficient to quantify the behavior of the focal individual using either recording rule (e.g., Anciães and Prum 2008; Bosholn et al. 2016; Durães 2009). In these cases, longer observation intervals would prevent recovering accurate information regarding when the behaviors were observed. On the other hand, in species with little activity or low mobility, it is suggested that the duration of observation intervals be longer. The three-toed sloth, for example, can remain inactive for many minutes and, for this reason, longer observation intervals are considered sufficient for good behavioral sampling (e.g., Urbani and Bosque 2007). In order to determine the duration of the observation interval it is also necessary to consider the number of behavioral categories that will be sampled. If the goal is to observe many categories (e.g., vocalizations, displays, agonistic interactions), short observation intervals might

not be appropriate for accurately sampling all intended behaviors. However, if observation intervals are too long, it might turn out to be difficult for the observer to concentrate during the entire sampling interval, which may affect the accuracy of the collected data (Altmann 1974).

Before beginning observations using focal animal sampling, it is important to determine which individuals will be observed. This choice will depend on the research goals. For example, if the research aims to study behavioral variation among adult females in a particular species, the observers should give priority to individuals of that sex and age category. Observers should then, ideally, observe as many individuals of the intended sex and age with equivalent sampling effort. This would allow more robust comparisons among individuals. After all, results would possibly be skewed by observing one individual for only 10 intervals while observing another for 120 intervals, which could compromise data comparison between individuals.

To determine the duration of the observation intervals, the most appropriate recording rules, and the number of individuals that can be sampled, it is recommended that observers conduct a pilot study before beginning the behavioral data collection using focal animal sampling. Without appropriate planning, many behavioral data might be in fact useless or obsolete. Besides that, pilot studies might be important both for the habituation of the focal individuals and for acquaintance of observers with the studied species. Additionally, they are essential to (i) correct minor errors referring to data collection not detected in the project proposal; (ii) observe the mobility of focal species and frequency/duration of behavioral categories, besides adjusting the duration of the observation intervals; and (iii) determine the total time of observation that will be necessary to obtain a complete sampling of the behavioral repertoire, besides obtaining enough replicates of the behaviors, for each sampled individual. From these pilot studies, the observers can elaborate the spreadsheet that will be used to quantify the different behaviors of focal individuals. This spreadsheet will vary according to the needs of

Local:Date:Observer:

Individual:Sex:Age:

| 06:05 am |                         |                         |                         |                              |
| 06:10 am |                         |                         |                         |                              |
| 06:15 am |                         |                         |                         |                              |

**Focal Animal Sampling, Fig. 1** Spreadsheet template to quantify behavioral data. Page header should contain general information such as localization of study area, date of observation, and observer identification among others if necessary. It is also essential to record the identification,

sex, and age of the focal individual. In the first column of the spreadsheet, the captions referring to the behavioral elements and additional considerations should be placed. In the lines, the durations of observation intervals should be placed

F

each observer and according to the characteristics of the focal species (Fig. 1). However, the observer should be aware that the data collected during the pilot studies should not be used in the posterior analyses. Even if the observer felt that little has been modified from the pilot study, the habituation of the observer with the object of study requires some time (1–3 days in simplest cases).

One of the advantages of focal animal sampling is a more detailed sampling if compared to other sampling methods (Altmann 1974). The amount of information sampled with focal animal sampling is relatively similar to that collected through other methods (e.g., ad libitum). However, the accuracy of the collected data is generally greater with focal animal sampling because it is possible to specify at which time the behaviors occurred. This method is thus recommended when observers intent to sample specific behaviors performed by each individual in a group (e.g., courtship ritual, parent/offspring conflict, female choice). Brodt et al. (2013), for example, used focal animal sampling to determine the dominance hierarchy of one lekking bird species. While, Anciães and Prum (2008) used focal animal sampling to study whether display behavior of some bird species changes with temporal changes in light conditions. Another advantage is that little information is lost when an individual is

observed through this method. However, focal animal sampling also has some disadvantages (Altmann 1974). This method requires a higher number of sampling records, inflating the required sampling effort in studies of large groups of individuals. In addition, during observations of free wild animals, the individual being observed might disappear. In these cases, the observer has two options: find again the focal individual or observe another individual (if the observer chooses the second option, observation data of the lost individual need not be discarded). Therefore, it is very important to consider that, despite the numerous advantages, focal animal sampling will not always be appropriate. In species which are very active and participate in large groups, for example, other observational methods (e.g., ad libitum, scan sampling, behavior sampling) can be used to maximize behavioral data sampling (e.g., termites, *Nasutitermes corniger* (Pequeno 2017); the pied tamarin monkey, *Saguinus bicolor* (Sobroza et al. 2017)).

## Definition

Controversial (see below): People’s and other animals’ commonsense or naturally-occurring understanding of the physical world (e.g., properties of objects, causality), especially as it relates to the manipulation of objects using tools. Of particular interest is whether this understanding consists of reasoning about unobservable physical mediators (e.g., transfer of force) or is based on observable features of physical events.

## Introduction

When a chimpanzee stands on a wooden crate and uses a pole to reach bananas suspended from the ceiling, what does the ape understand about its actions, the crate and pole, and the bananas? Does the ape think about the necessary conditions for the pole to function as a tool that can be used to get the bananas? Does this animal understand why these same objects (i.e., the crate and pole) cannot be used to procure water? When a capuchin uses a stone hammer to crack a nut placed on a stone anvil, what does the monkey understand about its actions, nuts, hammers, and anvils? Does this animal think about the conditions necessary for the hammer to crack the nut? Does the capuchin understand the concept of “hardness?” And when a child uses scissors to cut paper, what does she understand about her behavior, scissors, and paper? Does she think about the necessary conditions for the scissors to cut the paper? Does she understand that the

same effect cannot be achieved if a tool lacked “sharpness?”

These are the sorts of questions that interest anthropologists, biologists, philosophers, and psychologists who study folk physics. For these scientists and scholars, the proximate purpose of studying folk physics is to gather information about how people and other animals think about objects in their physical worlds and about physical causes and their effects (i.e., physical causality). Some of the dimensions of the physical world and causality that interest researchers are distance (how far), time (how long), quantity (how many), magnitude (how much), and frequency (how often). Some of the dimensions that are not directly observable include transfer of force and gravity. Although researchers want to discover if and how humans and nonhuman animals think about unobservable physical constructs, the domain of folk physics consists of those physical events that can be observed without sensory aids such as cameras, telescopes, microscopes, oscilloscopes, and the like. Phenomena of an astronomical, chemical, magnetic, and electrical nature are thus normally excluded from the study of humans’ and, for obvious reasons, animals’ folk physics. The ultimate purpose of studying folk physics is to develop a theory about the evolution of cognitive abilities.

The pursuit of evolutionary goals requires comparative methods, and the study of folk physics is no different. Although primates such as chimpanzees, gorillas, and capuchin monkeys are the animals whose folk physics is most often compared with that of humans, the folk physics of tool-using avian species such as New Caledonian crows and woodpecker finches also have been compared to the folk physics of people and other primates. Folk physics is studied in controlled laboratory experiments (e.g., Chappell and Kacelnik 2002), using naturalistic observation in field studies (e.g., Hunt 1996), by observing the behavior of captive animals (see Haslam 2013), and through computer simulations of animal robots (e.g., Chappell and Hawes 2012). But discovering what nonverbal

animals know about their physical world is not easy. The root of the problem is that it is unclear what folk physics is (a conceptual problem) and how it should be studied (a methodological problem).

## Conceptual-Methodological Challenges in the Study of Folk Physics

There are several challenges in the study of folk physics that fall along a conceptual-methodological continuum. At the conceptual end is a lack of clarity about the definition of folk physics: People’s and other animals’ commonsense or naturally-occurring understanding of the physical world. At the methodological end is a lack of clarity about how to study folk physics.

### What is “Understanding?”

The definition of folk physics is itself a source of two major conceptual challenges. The first concerns the term “understanding,” which is not a well-defined scientific concept (Pear 2001). As a result, a seemingly simple question such as, “Do chimpanzees understand weight?” or a more specific question such as, “Do chimpanzees form mental representations of unobservable causal mechanisms?” are difficult to answer. What counts as evidence of understanding weight? What counts as evidence that a chimpanzee formed a mental representation of an unobservable causal mechanism? In studies of concept learning, if a person or another animal makes a common response in the presence of stimuli that share specifiable characteristics, that is evidence that the subject understands the concept or class. Learning a concept thus depends on appropriate discrimination (i.e., identifying stimuli that are not part of a class) and generalization (i.e., identifying stimuli that are part of a class). For example, a child shows that he understands what “red” is if he says or writes “red” after someone asks, “What color is that?” while pointing to the red feature of various objects. Learning the concept “red” requires discriminating between red and other colors, as well as generalizing across varieties of red (e.g., burgundy, maroon, crimson). In relation

to folk physics, a chimpanzee that chooses rakes that are long enough to retrieve out-of-reach objects and does so while avoiding holes that can trap the object may be showing an understanding of the relations among a tool's length and an object's distance, that holes cannot support objects (and thus trap them), and perhaps even unobservable constructs such as transfer of force and gravity. Similarly, a chimpanzee that routinely tries to obtain water using pails, cans, and other containers instead of pails and cans without bottoms (which are thus merely tubes) may be showing an understanding of containment. But what counts as evidence of understanding has not been agreed upon. At a minimum, proof that a concept has been learned requires making a correct response across different situations.

### **What is "Common Sense" or "Naturally-Occurring" Understanding?**

The second conceptual challenge in the definition of folk physics is the adjective "commonsense," as in "commonsense understanding." Common sense is also not a well-defined scientific concept, and how it could apply to animals is even more ambiguous. According to Kuipers (1984), "commonsense causal reasoning is qualitative reasoning about the behavior of a mechanism which can be done without external memory or calculation aids" (p. 170). Davis (1990) defined common sense as "the common knowledge about the world that is possessed by every schoolchild and the methods for making obvious inferences from this knowledge" (p. 1). Entire articles have been written about commonsense reasoning without defining what it is.

Perhaps because of the difficulty of defining common sense, especially as it relates to animals, some researchers define folk physics in terms of naturally-occurring understanding instead of commonsense understanding. For example, Povinelli (2000) defined folk physics as understanding about the physical world that "develops naturally and spontaneously" (p. 2) in the course of development. A problem with this variant of the definition is that programmatically training animals to assess their folk physics disqualifies such research as studies of folk physics,

which is about naturally-occurring understanding or understanding that develops without explicit training.

A problem with restricting folk physics to naturally-occurring understanding is that the distinction between naturally-occurring (on the one hand) and explicitly-trained (on the other hand) may be artificial or unimportant. To illustrate, consider the following question: Is the understanding that results from teaching children to identify shapes programmatically trained or naturally occurring? Teachers and parents are a part of most children's natural environments. Teachers and parents may provide explicit feedback to a child's labeling of a shape, such as when a parent says, "That's right" or "No, that's a triangle." Is the child's eventual understanding naturally occurring or explicitly trained?

One solution to the problematic aspects of the adjectives "commonsense" and "naturally-occurring" is to eliminate them from the definition of folk physics. "Physical causality" and "physical cognition" are often used interchangeably with "folk physics." When researchers study physical causality, they are trying to discover if and how people and other animals reason about events that are associated with one another in space and time; specifically, whether organisms reason about unobservable mediating physical forces (e.g., gravity) or whether an organism's understanding is based on directly observable features of the events (e.g., a desired object falls out of reach) (Visalberghi and Tomasello 1998). Unlike the study of folk physics, the study of causal understanding in the physical domain (i.e., physical causality) has no restrictions about the conditions under which this understanding develops. Similarly, physical cognition refers to "how an organism understands and manipulates its physical world" (Parrish and Brosnan 2012, p. 174), again, without any restriction on how this understanding is acquired or that it relates only to causality. At present, though, there is no consensus as to whether physical causality, physical cognition, and folk physics are the same or different, or whether the definition of folk physics should contain the adjectives commonsense, naturally-occurring, or intuitive.

### Why Does the Definition of Folk Physics Matter?

The definition affects the methodology used to study folk physics and the interpretation of the results of experiments that purport to study it. To see how, consider that the study of folk physics is characterized by two approaches. In one approach, researchers specify an aspect of folk physics that adult humans possess, such as knowing that objects fall because of gravity or that a rigid rake is necessary to retrieve a heavy object. These researchers then devise physical puzzles to test if nonhuman animals or children possess the same knowledge. Relative to a variety of control problems, solving the puzzles should only be possible if the subject possesses the relevant knowledge. Without this knowledge, subjects should make many errors or otherwise be incapable of solving the problem. For example, pigeons do not seem to have knowledge of “insideness.” When presented with 80 images of simple curves with a single dot either inside or outside a curve, these birds had a great deal of difficulty categorizing the two types of images: those of curves with a dot on the inside versus a dot on the outside (Herrnstein et al. 1989). Had the pigeons spontaneously sorted the two types of images or, after extended training, been able to sort novel images of curves with a dot on the inside or outside, researchers would have concluded that the pigeons understood insideness.

In the second approach, which is exemplified by Povinelli’s (2000, 2012) studies of folk physics, researchers also specify an aspect of folk physics that adult humans possess, devise physical puzzles to test if animals or children possess the same knowledge, and use a variety of control problems. But unlike studies that fall neatly into the first approach, in the second approach, explicit training is kept to a minimum and consists of what is normally considered pretraining – trials to familiarize the subjects with the testing environment, procedures, and equipment (e.g., tools). Attempts to explicitly train understanding invalidates, by definition, an examination of a subject’s naturally-occurring understanding of its physical world. “Determined to demonstrate similarity [between humans and other species], many researchers train on, without ever seriously

considering the possibility that the very extent of the efforts required to produce human-like behaviors in their animals undermines the very claims they wish to make in the first place” (Povinelli 2000, p. 338). Also unlike the first approach, the second approach relies on testing subjects using increasingly difficult variations of the physical puzzles to discover the limits of the subjects’ understanding. These limits are then compared to adult humans’ purported understanding of similar or related phenomena.

These two approaches can come into conflict. If a study used the second programmatic-training-not-allowed approach and failed to find evidence of abilities in animals comparable to those of adult humans, researchers who use the first programmatic-training-allowed approach could argue that the absence of evidence could be because the animals lacked the relevant concept, because of a lack of motivation, because of the subjects’ experiences prior to testing, because of poorly designed tests, or because of many other reasons (see Buckner 2013; Machado and Silva 2003). In short, researchers who use the first approach would not necessarily conclude that absence of evidence is evidence that the ability is absent. Proponents of the second approach, though, could conclude that absence of evidence is evidence of absence.

Similarly, if animals trained to learn a concept seemed to possess an understanding comparable to that of humans, proponents of the programmatic-training-allowed approach could conclude that they discovered a similarity between humans’ and animals’ understanding. But proponents of the programmatic-training-not-allowed approach may disagree. They could argue that what was demonstrated was that animals can be trained to behave like humans on a particular task or set of tasks, not that the people’s and animals’ folk physics were similar.

The cost of these conflicting approaches, which are rooted in different definitions of folk physics, is that it is unclear what scientists and scholars know about different species’ folk physics. Proponents of the programmatic-training-allowed approach, which is rooted in a definition of folk physics without the terms commonsense or

naturally-occurring, can claim that, “Because Species A behaved similarly to Species B across several tasks, we conclude that these two species have a similar understanding of physical concept X.” Proponents of the programmatic-training-not-allowed approach, which is rooted in the definition of folk physics that contains the terms commonsense or naturally-occurring, could claim that, “Because the two species behaved similarly only after extensive training, the results do not show that these species’ folk physics were the same.” In sum, what is known about the comparative study of folk physics depends on who you ask, this person’s preferred definition of folk physics, and this person’s preferred approach to the study of folk physics.

## Folk Physics: Contrasting Evidence

### Weight

Chimpanzees and other primates (e.g., capuchin monkeys) use hammers and anvils to crack nuts so that the desired kernel can be obtained. One variation of this nut-cracking behavior involves placing the nut on a stone anvil and then hitting the nut with the flat side of a hammer stone. Mastering nut cracking requires that the animal “attends to the properties of the tool that are relevant for reaching the goal of cracking the nut” (Schrauf et al. 2012, p. 1). Wild chimpanzees select hammers of a particular size, shape, and material that can be used to effectively crack the nut. Wild capuchins select stones that are best suited for cracking nuts.

To answer the question, “Do chimpanzees use weight to select hammer tools?” Schrauf et al. (2012) presented captive chimpanzees with cuboid-shaped (one experiment) and spherical (another experiment) hammers identical in every way except their weights. Although the chimpanzees did not have an initial preference for the weight of the hammer they used to crack the nut, they eventually developed a preference for heavier hammers that required less time and fewer hits to open the nuts. Because all hammers in a given experiment differed only in terms of their weights, the results showed that chimpanzees learned to attend to a key property of the tool

(namely, its weight) relevant to the problem (i.e., cracking nuts).

These results suggest that chimpanzees’ folk physics consists, at least to some extent, of an understanding of weight. At a minimum, their understanding consists of being able to perceive and differentiate weight as a property of objects. But the significance of these results is unclear because the ability to discriminate objects by weight required many trials (learning), which leads to questions about the animals’ *naturally-occurring* understanding of weight. Also, without generalization (transfer-of-training) tests to determine whether the chimpanzees can use what they know about weight to solve novel problems, it is difficult to say what they understand about weight. Analogously, if a psychologist was investigating what a child understood about colors, and the results of an experiment showed that the child could, after many trials, reliably select a red object that was associated with a reward instead of green or yellow objects that were not, few psychologists would conclude that the child understood the property “color.” Before concluding that the child understood color, psychologists would test if the child could identify the correct color in a variety of circumstances, across many problems. That is, psychologists would test for evidence of concept learning. Without generalization tests, the strongest conclusion is that the child can differentiate objects on the basis of color, or that the child can associate different colors with different outcomes. This is one reason why after more than 30 experiments to determine what chimpanzees understood about weight, Povinelli (2012) concluded that, although these animals understand many aspects of weight, they do not reason about it as an abstract concept.

In the absence of programmatic training, New Caledonian crows, a tool-using avian species, do not differentiate between heavy objects, which could be dropped into a tube to trigger the release of food, and lighter objects, which lacked the weight to produce the force needed to release the food. After explicit training, though, the birds learned to select the heavier objects that caused the release of food (Neilands et al. 2016). These results suggest that New Caledonian crows’ folk

physics consists of the ability to differentiate objects on the basis weight. But, again, the importance of these results is hazy because the ability to discriminate between heavy and light objects required programmatic training. If folk physics is about naturally-occurring, commonsense, or intuitive understanding, then training to produce that understanding undermines the target of the investigation (Povinelli 2000).

### Gravity

Rooks are birds that are not known to use tools in the wild. They can, however, in laboratory settings use tools to obtain a desired reward. For example, rooks can shape wire to produce a hook, and use several tools in a sequence to obtain a reward (e.g., picking up a stone and dropping it into a vertical tube to obtain access to food). These birds may even “possess an understanding of tools rivaling habitual tool users such as New Caledonian crows and chimpanzees” (Bird and Emery 2009, p. 10370).

Rooks’ understanding of gravity has been tested using a trap-tube task, a problem that is commonly used to study chimpanzees’ and other primates’ folk physics. The trap-tube consists of a clear tube from which animals can extract a reward if they can avoid pushing or raking it into a trap. The most commonly used trap-tubes have one or two traps (see Fig. 1, top panel). An experimenter can disable a trap by inverting it (see Fig. 1, bottom panel). In this position, a trap

does not function as a trap. What an animal understands about the task is often measured in terms of how many trials it takes the animal to avoid a functional trap and whether the animal will continue to avoid the trap when it is inverted into a nonfunctional position. “The rationale is that, if they understand that unsupported items fall under gravity, they will also understand that an inverted trap cannot endanger the item” (Chappell 2006, p. R244).

Using a programmatic-training-allowed approach, rooks learned to solve the trap-tube problem by pulling a stick that retrieved the reward; pulling the wrong stick caused the reward to fall into the trap (Seed et al. 2006). To see if the birds could transfer what they learned about the trap-tube to new circumstances, the experimenters presented the rooks with two novel problems. When the new problem consisted of a relatively minor variation of the initial trap-tube, the rooks solved the problem (i.e., avoided the trap). However, when the new problem was more dissimilar to the initial trap-tube that the rooks had learned to solve, most of the birds failed to avoid the trap. Because most of the rooks did not transfer what they learned about one physical task (i.e., the initial trap-tube) to this novel task which had the same underlying causal structure and unobservable construct (i.e., the role of gravity), the researchers concluded that “it seems unlikely that they [the rooks] had an understanding of the unobservable causal properties of the task” (Seed

**Folk Physics, Fig. 1** Schematic of the trap-tube problem. Top panel illustrates tubes with functional traps. The arrow indicates the direction that the desired object (blue cube)

must travel to be retrieved. Bottom panel illustrates tubes with inverted (nonfunctional) traps. The desired object can be retrieved by moving it in either direction

et al. 2006, p. 700). Based on the success of the one rook that successfully solved both novel problems, the researchers suggested that although physical cognition may involve reasoning about unobservable forces, it could also consist simply of forming rules based on strictly observable features of a problem (Seed et al. 2006).

Great apes (gorillas, chimpanzees, bonobos, orangutans) presented with similar tasks designed to assess their understanding of the properties of the trap also learned to solve the problems, but did not transfer what they learned to novel tasks. The researchers concluded “that nonhuman great apes may know more about the relation between traps, rewards and tools than previously thought. This knowledge, however, may be task specific and may not easily permeate across tasks, perhaps due to a limitation in apes’ analogical reasoning abilities” (Martin-Ordas et al. 2008, p. 430).

These and other studies show that nonhuman animals can learn to solve problems with a trap whose action depends on gravity. What these studies demonstrate about nonhuman animals’ naturally-occurring understanding of their physical worlds is debatable. In most cases, animals are first trained to solve a problem, and doing so undermines the study of folk physics according to proponents of the programmatic-training-not-allowed approach. Also, adult humans who supposedly understand the underlying causal structure of simple tool-use tasks sometimes behave like other animals, which raises questions about the conceptual foundations of some studies of folk physics and the methods used to study it (see Silva and Silva 2006). In addition, although transfer tests are important methods for ascertaining what subjects have learned, the inability to generalize from one problem to another with similar unobservable properties may not reveal much about what an animal understands (Machado and Silva 2003). Generalization is often unlikely, even in humans, without explicit generalization training (Stokes and Baer 1977).

### Support

Jean Piaget’s (1952) support problem has been used to study both humans’ and animals’ understanding of means-end connections as related to physical support. This sort of problem consists of

a desired but out-of-reach object (e.g., a toy) that is placed on a supporting object (e.g., a blanket) that is within a subject’s reach. The desired object can thus be obtained by the subject pulling the blanket and dragging the object so that it is within reach.

In one variation, a chimpanzee is presented with the choice of pulling a blanket with a piece of food on it or pulling a blanket with a piece of food beside it. The ape should pull the first blanket if it understands the necessary relation between the supporting object and obtaining the desired object. Although some chimpanzees will make the correct choice without having been trained to do so, their behavior is controlled by what they see. As a result, these animals fail to solve transfer of training tests that are perceptually dissimilar but causally similar to the task they previously solved (Povinelli 2000). And the same appears to be true of dogs. Using a programmatic-training-allowed approach and novel tasks to assess the canines’ understanding of support, researchers discovered that dogs learn to solve support problems based on perceptual cues (i.e., what they see), not an understanding of the underlying (unobservable) causal structure (Müller et al. 2014). But, again, depending on a scientist’s or scholar’s definition of folk physics and the methods used to study it, the veracity of these conclusions is questionable.

People’s and animals’ understanding of support relations have also been studied using a violation-of-expectation paradigm, an approach that relies on habituation – a comparatively simple form of learning, but explicit training nonetheless. To test children’s folk physics related to support, a psychologist could present children with a stimulus that consists of a target object (e.g., an attractive box or a toy) and a platform (e.g., an inverted crate) that could support the target object. The target object might be placed completely on the platform (i.e., fully supported), partially on the platform (i.e., partially supported), “magically” floating next to the platform (i.e., unsupported), and in various other combinations to determine what children understand about the physical aspects of support (e.g., amount of contact, center of gravity) (see Fig. 2). What infants understand is assessed using a violation-of-expectation

**Folk Physics, Fig. 2** Schematic of support relations configurations. Top row: The target object (light cube) is fully supported by the platform (dark cube). Middle row: The target object is partially supported. Bottom row: The target object is unsupported

paradigm. The key feature of this paradigm is, after some training that consists of habituation, the measurement of the cumulative amount of time that a subject looked at several presentations of different configurations. If what a subject is looking at is inconsistent with her expectations about the physical world, she will be surprised by what she sees and will thus stare longer at the scene than if what she is looking at is consistent with her expectations. In the latter case, the configuration of the target object and the platform will not elicit surprise and thus the subject will spend less time looking at this scene. In short, because impossible configurations violate children's expectations, these configurations are more surprising and novel than possible configurations; the

more novel and surprising an event, the more time the child will spend looking at it.

Based on differences in looking times at different configurations (possible vs. impossible), psychologists have concluded that by 3 months of age, children's understanding of support is that the target object can be supported as long as it is in contact with the platform. Between 3 and 6.5 months of age, children become aware that the locus and amount of contact between the object and the platform are important determinants of the whether the object can be supported. Thus, by about 6.5 months of age, children expect the object to fall if a significant portion of its bottom surface is not in contact with the top of the platform (Baillargeon 1994).

When chimpanzees were shown video clips of objects in physically possible (e.g., a banana supported by a box) versus physically impossible (e.g., a banana floating in the air near a box) support relations, these animals spent more time looking at the impossible relations (e.g., Cacchione and Krist 2004). These results and others led Cacchione and Krist to conclude that chimpanzees have some expectations about support relations that are "based on the perceived contact relation between two objects, both qualitatively (contact vs. no contact) and quantitatively (sufficient vs. insufficient amount of contact)" (p. 147). Although these studies of people's and other animals' understanding of support deviate somewhat from the two major approaches for studying folk physics, there are questions about the validity of the violation-of-expectation approach (e.g., Clearfield and Westfahl 2006).

## Conclusion

The study of folk physics is controversial and fractious (Buckner 2013). The sources of these divisions are many: conflicts between camps of researchers characterized accurately or inaccurately as "overestimators" or "killjoys" of non-human animals' abilities, tensions about what is folk physics, disputes about the value of naturally-occurring learning versus programmatically-trained understanding, disagreements about the significance of understanding based on inferences

about what is seen versus what is unseen, debates about what are the right tests to assess different species' understanding of their physical worlds, and arguments about whether the existence of reasoning about unobserved forces can be reduced to simple "yes" or "no" answers. Add to this list philosophical debates about the role of language: Is it even reasonable for a nonverbal creature to infer abstract causes such as gravity or transfer or force (Machado and Silva 2003)? The philosopher Wittgenstein (1958) remarked, "We say a dog is afraid his master will beat him; but not, he is afraid his master will beat him tomorrow. Why not?" (p. 166e). It is because it seems impossible to learn the concept "tomorrow" effectively without language. The same may be true of concepts such as weight, gravity, and support. But folk physics need not be primarily about reasoning about unobservable forces (Seed et al. 2006). "Rule abstraction and the formation of representations based on observable features" [emphasis added] may explain why some animals "have the ability to form sophisticated cognitive solutions to physical problems in the absence of causal understanding of unobservable forces" [emphasis added] (Seed et al. 2006, p. 700). This sort of emphasis on reasoning about observable features provides a means of studying physical cognition using established methodologies from the study of concept learning and associated frameworks from which to compare the results (e.g., Vonk and MacDonald 2002; see also Zentall et al. 2014).

## Food Calls

Julie Gros-Louis

Department of Psychological and Brain Sciences,  
University of Iowa, Iowa City, IA, USA

## Synonyms

Food-associated calls; Food-associated vocalizations; Food-related calls

## Definition

Vocalizations that are produced while foraging and/or feeding.

Food calls, also known as food-associated calls, occur in several animal species and are emitted upon discovering food and during foraging/feeding bouts (primates: *Cebus capucinus*, Boinski and Campbell 1996; *Cebus apella*, Di Bitetti 2003; *Ateles geoffroyi*, Chapman and Lefebvre 1990; *Saguinus oedipus*, Cleveland and Snowdon 1982; Roush and Snowdon 2000; *Saguinus labiatus*, Caine et al. 1995; *Callithrix jacchus*, Vitale et al. 2003; *Callithrix geoffroyi*, Kitzman and Caine 2009; *Leontopithecus rosalia*, Benz et al. 1992; *Cebuella pygmaea*, Pola and Snowdon 1975; *Macaca mulatta*, Hauser and Marler 1993; *Macaca sinica*, Dittus 1984; *Pan troglodytes*, Hauser et al. 1993; Wrangham 1977; *Pan paniscus*, van Krukowski et al. 1996; *Gorilla g. gorilla*, Luef et al. 2016; naked mole rats: *Heterocephalus glaber*, Judd and Sherman 1996; dolphins: *Tursiops truncatus*, Janik 2000; greater spear-nosed bats, *Phyllostomus hastatus*, Wilkinson and Boughman 1998; avian species: *Gallus domesticus*, Marler et al. 1986; Evans and Marler 1994; *Passer domesticus*, Elgar 1986a; *Hirundo pyrrhonota*, Brown et al. 1991; *Corvus corax*, Heinrich 1988; Heinrich and Marzluff 1991). In some species, food calls are a distinct call in the vocal repertoire (e.g., Geoffroy's marmoset, domestic chickens), whereas in others, the calls emitted in a feeding/

foraging context are also emitted in other nonfood-related contexts (e.g., toque and rhesus macaques, spider monkeys, red-bellied and golden-lion tamarins, bottlenose dolphins, and greater spear-nosed bats among others).

Food calls across species have a range of different functions (Clay et al. 2012). Only a few species have what are traditionally labeled “functionally referential” food calls. To be “functionally referential” (Macedonia and Evans 1993), calls first must be given exclusively in a feeding context and have a unique acoustic structure relative to other calls in the vocal repertoire (production criterion). Second, animals who hear the calls show feeding-related behaviors even in the absence of food (perception criterion). Calls of domestic chickens (Evans and Evans 1999) and Geoffroy’s marmosets (Kitzman and Caine 2009) fit the production and perception criteria for functional reference. Domestic chickens who hear playbacks of food calls will fixate downwards and search the substrate, both of which are anticipatory feeding behaviors (Evans and Evans 1999). Similarly, Geoffroy’s marmosets show more foraging and feeding behaviors following playbacks of food calls compared to control calls (Kitzman and Caine 2009). The question of whether calls contain information and/or are functionally referential has long been debated and there has been recent renewed interest in this issue (see Clay et al. 2012; Carazo and Font 2010; Rendall et al. 2009; Seyfarth et al. 2010; Wheeler and Fischer 2012).

## Function of Food Calls

There are a number different hypothesized functions of food calls. The information-sharing hypothesis suggests that calls attract individuals who are out of visual contact to inform others about the presence of food (Dittus 1984; Brown et al. 1991; Evans and Evans 1999; Hauser and Marler 1993; Vitale et al. 2003). In socially foraging species, such as cliff swallows (*Petrochelidon pyrrhonota*; Brown et al. 1991), it makes sense to inform others about food for group foraging; food calls attract conspecifics, which

results in more insects becoming available as they are stirred up by increased activity of more birds and tracking the swarm is more effective (Brown et al. 1991). Food calls also function to attract others who, in turn, help to monopolize food (ravens: Heinrich and Marzluff 1991; Wilkinson and Boughman 1998). For example, in ravens, “haa” food calls attract others who, in turn, help to cooperatively defend the food source (Heinrich and Marzluff 1991; see also Bugnyar et al. 2001). In these species, it is beneficial to attract others to increase efficient and successful foraging.

In other species, it is less clear why individuals would share information about food, given that it can come with a cost; experiments in tufted capuchins (*Cebus apella*) showed that individuals who called more quickly after finding food ultimately consumed less than individuals who had a longer latency to call (Di Bitetti and Janson 2001). In addition, in white-faced capuchins (*Cebus capucinus*), aggression can be high in feeding contexts; dominants can displace or attack subordinates to steal food or drive them from a feeding source (Perry 1996, 1997; Gros-Louis 2004a). Therefore, other functions of food calls have been proposed to explain the benefits to the signaler of calling.

Studies that have assessed why signalers produce food-associated calls has revealed a number of possible functions: to attract mates (bonobos: van Krunkelsven et al. 1996; chimpanzees: Kalan and Boesch 2015; domestic chickens: Evans and Marler 1994; Pizzari 2003; Marler et al. 1986b), to decrease predation risk (house sparrows: Elgar 1986b; red-bellied tamarins: Caine et al. 1995; Newman and Caraco 1989), and to regulate spacing between foraging individuals (big brown bats, *Eptesicus fuscus*, Wright 2014; pied babblers, *Turdoides bicolor*, Radford and Ridley 2008). For example, in white-faced capuchins, nearest neighbor distance increases following food calls, suggesting that food calls help to regulate spacing during foraging (white-faced capuchins, *Cebus capucinus*, Boinski and Campbell 1996). Furthermore, experimental studies found that calls are produced more in the presence of a higher ranking individual, which decreases the likelihood of the caller receiving aggression and/or

experiencing food theft. These findings were corroborated with focal observations (Gros-Louis 2004a). Thus, calls may serve to announce ownership, thereby decreasing aggression (see also Hauser and Marler 1993).

Recent studies that have explored social factors associated with calling have revealed more subtle functions. Male chimpanzees emit more food calls when social partners, particularly those who are higher ranking, are nearby and are proposed to serve to maintain affiliative relationships (Schel et al. 2013). Furthermore, individuals who hear food-associated calls (“receivers”) were more likely to remain in the food patch, suggesting that the calls function to maintain cohesion during prolonged feeding bouts with preferred partners (Fedurek and Slocombe 2013). By contrast, in Western chimpanzees (*Pan troglodytes verus*), researchers (Kalan and Boesch 2015) found that males produce more food calls when oestrus females are nearby, which serves to attract females to food sources thus increasing mating opportunities. Therefore, there might be different functions of food calls in different populations, which suggests flexibility in pragmatic use of calls, a new and fruitful research topic in primate communication (Scott-Phillips 2010; Wheeler and Fischer 2012).

Regardless of the possible function of food calls for signalers, individuals who hear the call can benefit by knowing the presence and location of a food source. This distinguishes different functions for signalers and recipients: if the probability of listeners hearing call A in context X is very high and, conversely, context X rarely occurs in the absence of call A, call A comes to have high predictive value of context X (for further discussion, see Seyfarth and Cheney 2003). Playback studies in white-faced and tufted capuchins demonstrated that individuals were more likely to approach when they heard food calls than when they heard control calls (Gros-Louis 2004b; see also Di Bitetti 2003). Observations in other species also support these findings (e.g., primates: *Ateles geoffroyi*, Chapman and Lefebvre 1990; *Macaca sinica*, Dittus 1984; dolphins: *Tursiops truncatus*, Janik 2000; greater spear-nosed bats: *Phyllostomus hastatus*, Wilkinson and Boughman

1998; avian species: *Gallus domesticus*, Marler et al. 1986a; *Passer domesticus*, Elgar 1986; *Corvus corax*, Heinrich 1988). Food calls thus can be considered a source of public information that indicates the presence of food (Valone 1996; Janik 2000).

## Effects of Food Quantity, Preference, and Quality

Studies have shown that food call rate and acoustic structure can vary as a function of food quality and food quantity. It is more common for call rate to vary rather than acoustic structure, suggesting that food calls may reflect arousal related to food quantity or quality, rather than something specific about the type of food. For example, East African chimpanzees call more when encountering large divisible food sources (Hauser et al. 1993). In addition, New World monkeys have been shown to produce more calls when encountering larger quantities of food and when they encounter fruit compared to other food types (Benz 1993; Caine et al. 1995; Elowson et al. 1991). These observations are consistent with findings in different species of capuchins (Boinski and Campbell 1996; Di Bitetti 2005; Gros-Louis 2004a; Robinson 1982), suggesting that call rate can increase with both food quantity and/or food quality. Rhesus macaques call at higher rates in the presence of high-quality food and call less for lower quality food (Hauser and Marler 1993). Ravens also produce a specific call (“haa” call) at higher rates when meat is discovered compared to other items. Therefore, calls may reflect a preference for presumably higher quality food, possibly mediated by arousal. Similarly, domestic chickens and white-tailed ptarmigan call more when they encounter better quality food (Marler et al. 1986a; Clarke 2010). In white-tailed ptarmigan, food calls are given proportionally more to higher protein foods, and chicks eat more of the items that receive food calls, suggesting a role in the development of diet selection (Clarke 2010; see also Wauters and Richard-Yris 2002).

Food call acoustic structure can vary as a function of individual food types and/or size of

feeding patch, although this pattern of call variation is less common (or less well studied). West African chimpanzees produce higher pitched calls for smaller trees, but also for preferred fruits. Furthermore, the pitch of calls produced for presumed preferred fruits varied as a function of patch size. Lower pitch calls were produced in larger patches and conspecifics tended to approach low-pitched calls (Kalan et al. 2015). Captive studies have also demonstrated that acoustic structure of food calls vary as a function of preference, with higher fundamental and peak frequencies also being produced in the presence of preferred food items (Slocombe and Zuberhubler 2006); however, the study on food preference associated with call variants has not been replicated in the wild. A recent study has also shown that rather than emitting different acoustic variants of a single call, bonobos combine calls into sequences in patterns that reflect individual food preferences and relate to the quality of food (Clay and Zuberbuhler 2009).

In summary, in a few species, food calls are a unique call in the vocal repertoire; more commonly, food calls are associated with feeding contexts but also occur in other contexts. Food calls rate and/or acoustic structure has been shown to vary with food quantity, quality, or preferences. In the few species in which food calls are produced only in feeding contexts, individuals perform specific foraging and feeding-related behaviors after they hear the call, whereas, in other species, food calls attract others, regulate spacing between foraging individuals, or relate to affiliative relationships. Because of the variability in call production and responses to food calls in different species, there are a range of hypothesized functions for food calls across taxa (see Clay et al. 2012).

## Food Neophobia

Klaudia Modlinska

Institute of Psychology, Polish Academy of Sciences, Warsaw, Poland

Food neophobia is a term established by Barnett (1958) for the fear of eating new food and hesitation to ingest it. It is common in many species, e.g., rats, mice, dogs, turtles, domestic ruminants, nonhuman primates, and some species of birds, such as crows or blue jays. This phenomenon was first observed and documented as early as in the eighteenth century, when a certain rat catcher observed that rats need to familiarize themselves with the food-bait before accepting it as food. Food neophobia is a specific type of neophobia, which is a fear-like response to a novel stimulus. However, this reaction to the novelty of edibles plays a crucial role in animals' survival. It is particularly relevant to omnivores/generalists, whose diet may be very broad but which need to distinguish between edible and inedible food. This problem is called "the generalist's dilemma" (Rozin 2000). Researchers claim that many animals will not eat unfamiliar food, when they first encounter it. This behavior may persist for several days and may be more pronounced in an unfamiliar environment. When an animal notices a novel object in its environment, it has to overcome the

initial fear of novelty and assess the properties of the object. Next, it has to recognize it as potential food and determine the consequences of consuming it. Novelty of food may be due to changes of food location, a container in which the food is presented, and food properties. The fear of a new container may be significantly stronger than food neophobia itself, which may suggest that animals assess any new food in two steps: first by assessing the novelty of an object and only then by assessing the food itself. Therefore, animals' responses to novel food result from an interaction of behaviors motivated by curiosity about the novel object's potential value and fear of possible threat or toxicity. However, if an animal overcomes its neophobia and the new food does not become associated with adverse bodily symptoms, the intake of food increases, and the preference for the particular feed persists (Barnett 1963, 2009). The hungrier the animal, the quicker it starts to eat unfamiliar food. Animals can develop an aversion to foods that cause illness even after a couple or dozen hours. It should be stressed, however, that food avoidance may be due not only to neophobia but also to the low palatability of a specific food item or individual food preferences. Food neophobia may be also mediated by prior subsequent food-related illness or conditioned taste aversion toward similar odors or flavors.

Although the neural mechanisms of food neophobia are still unknown, the brain structures that most probably take part in regulating its occurrence may be the gustatory cortex, the gustatory thalamus, and the medium nucleus of the amygdala.

Caution toward unfamiliar foods and preference for known sources of nutrition have an adaptive value. Individuals that enrich their diet with new items display an advantage over species specializing in one type of food only. However, while the environment offers many potential food sources, some food may be toxic or unpalatable. Studies carried out on wild-type rats (Modlinska et al. 2015; Modlinska and Stryjek 2016) show that the level of food neophobia depends on the developmental history of a specific individual.

It seems that animals that experience high levels of environmental variability on a daily basis do not develop food neophobia to the extent observed in animals living in stable conditions. Some researchers have suggested that pest control activities may have enhanced food neophobia in rats (Barnett 2005; Taylor and Thomas 1989). For example, food neophobia seems to be absent in Norway rats inhabiting landfills, where constant environmental changes provide ubiquitous contact with novelty of varying character and value (Barnett 1963). Absence of food neophobia has also been reported in a group of *Rattus norvegicus* that lived on an isolated island for over a century (Taylor and Thomas 1989). Therefore, the variability of the environment may result in a lower threshold for food neophobia. The behavioral plasticity in rats, as a response to changeable environmental conditions, suggests that the mechanisms underlying food neophobia must originate in ontogenesis and relate to ecological impacts. It may be concluded that environmental variability prompts omnivorous animals to reduce their food neophobia. In other species, however, the mechanisms underlying food neophobia may be related to the level of the animal's cognitive complexity, the group's social structure, and the level of complexity of social relations.

Relying on others' knowledge about palatability of foods, copying ingestive behaviors of other individuals, and following them to food sources reduce food neophobia by decreasing the uncertainty linked to food novelty. Food preferences of other group members provide information on which foods are safe to eat. By adopting those preferences, an animal decreases the risk of eating new foods and reduced the cost of individual learning by saving time that would otherwise be spent collecting information already accessed by other group members.

In animal ontogenetic development, the process of learning how to distinguish between food and other objects and selecting foods that are palatable is a key step. Studies on rats show that food neophobia in young individuals is expressed by avoidance of foods which they do not know.

At an early stage of an animal's life, it is one of the parents (the mother in most species) that provides information about palatable foods. In mammals, the first contact with the mother's diet occurs already in utero. By swallowing the amniotic fluid, these animals become familiar with the flavors and odors of food eaten by the mother. In this way, they obtain information about the types of food that are safe to consume and develop specific food preferences. This process continues at the suckling stage. The mother's milk is rich in flavors and odors of food she consumed. What is more, the odor of food the female ingested lingers on her mouth and fur.

After the weaning period, offspring stay in close proximity to their parent or parents and follow them to food sources. Consequently, young individuals ingest the same food as the parents and avoid foods that are not eaten by them. However, it must be stressed that juveniles do not learn which foods to avoid but rather develop preferences for the foods their parent ingest and are cautious toward any other potential feeds. Moreover, other adult group members have a major influence on food preferences in young animals by providing access to food sources and cues about properties of the types of food preferred by the group (Galef 1981). For example, in monkeys, youngsters spend most of their time close to adults, which, in addition to allowing them to passively familiarize themselves with foods consumed by the group, enables them to feed on other individuals' leftovers and to snatch pieces of food from other group members. In these species, adult individuals may also share their food with their offspring. Studies on capuchin monkeys show that the influence of the group on reducing the level of food neophobia is positively (asymptotically) correlated with the number of other individuals that are eating. An individual that has observed the behavior of the group eats more of the new food if the group is bigger (e.g., Visalberghi and Addessi 2000). A similar result was obtained in studies on rats (e.g., Galef et al. 1990).

Although neophobic behaviors may be triggered by basic phylogenetically shaped

mechanisms, the process of reducing or overcoming food neophobia seems to originate in learning, including various forms of social learning.

## Synonyms

[Artificial food patches](#); [Artificial foraging trays](#); [Foraging patches](#); [Foraging trays](#)

## Definition

Patch used to quantify one of an individual’s three foraging costs.

Artificial food patches have a wide variety of uses in the study of animal behavior. Optimal foraging theory (Charnov 1976; Stephens and Krebs 1986), specifically patch use theory (Brown 1988, 1992), provides a conceptual framework for understanding how food patches can be used to assess an individual’s foraging costs. Assuming an individual experiences diminishing returns while foraging in a depletable food patch, Brown’s (1988) model predicts that an optimal forager should cease foraging, in lieu of exploiting other patches or engaging in other activities, when its instantaneous patch harvest rate is equal to the sum of its metabolic, missed opportunity, and predation costs, which together form its foraging costs. When the amount of food within a patch is proportional to an individual’s harvest rate, the giving-up density (i.e., the resource density at the point at which an individual quits foraging in a patch) provides a surrogate of the patch quitting harvest rate. Therefore, the variation in giving-up densities across multiple food patches can be used to quantify changes in one of an individual’s foraging costs by holding two of the three foraging costs constant, often through experimental manipulation.

Proper construction and collection of artificial food patches is critical to ensure the giving-up densities collected are representative of the quitting harvest rate of the targeted species or

individual. Use of a substrate within the patch itself is necessary to generate diminishing harvest rates as the tray is depleted by the forager. In addition, all nontarget species must be excluded from foraging from patches either through physical construction or temporal availability. A habituation period where the targeted foragers are given time to locate and begin foraging within the food patches is required. The experimenter should the habituation period to ensure all nontarget species are excluded and, if necessary, to adjust the amount of food and/or substrate that is necessary to ensure the target forager is unable to forage the patch down to a zero density.

The use of artificial food patches to quantifying different aspects of an individual's foraging cost has been varied and widespread. Giving-up densities from artificial food patches have been shown to change appropriately in response to a forager's metabolic (Kotler et al. 1999), missed opportunity (Brown 1988), and predation costs (Schmidt et al. 2008).

## Foraging by Honeybees

Ash Samuelson and Ellouise Leadbeater  
School of Biological Sciences, Royal Holloway  
University of London, Egham, UK

### Introduction

The foraging behavior of a honeybee colony (*Apis mellifera*, L.) represents one of the most sophisticated examples of cooperative behavior in the animal kingdom and has arisen as the evolutionary product of an unusual and highly complex social system. Honeybees are advanced eusocial insects, defined by overlapping generations, cooperative brood care, and reproductive division of labor. In each colony a single queen is almost always responsible for the vast majority of the reproductive output, with the functionally sterile workers (her daughters) helping to rear their sisters (other workers and new queens) and brothers (drones). The colony therefore functions as a single reproductive unit, with the workers sharing a common goal: to optimize foraging effort in a manner that allows the colony to grow in size until the entire group can reproduce by splitting, in a process known as swarming. Seeley (1989) and others have thus described the colony as a “superorganism” – an individual entity with many of the attributes of an organism, but itself composed of individual organisms. Consequently, a discussion of foraging behavior in this species must include both the behavior of the individual units, the workers, and the colony-level behavior of the “superorganism” as a whole as it efficiently

exploits the surrounding resources to sustain itself.

Honeybees are central place foragers. Although domestic colonies reside in hives that are managed by beekeepers, such hives mimic the hollow tree cavities that are the species’ natural nest sites. Inside the nest, the workers build sheets of vertical wax comb made up of hexagonal cells in which food is stored and brood (young bees) are reared. From that base, a subset of the workers, the foragers, leave to collect resources from the environment and bring them back to the nest. Tasks in the colony are allocated by age, with younger bees performing less risky tasks inside the nest such as nursing brood and food processing and switching to the more hazardous task of foraging toward the end of the lifespan. Foragers can travel up to approximately 14 km to collect food, although typically 95% of foraging trips are within 6 km in a temperate environment. This represents a foraging area of 100 km<sup>2</sup>, partially reflecting the enormous requirements of a colony typically comprising around 30,000 animals. This demand represents a considerable foraging challenge: a honeybee colony in a temperate climate must collect approximately 120 kg of nectar, 20 kg of pollen, 25 l of water, and 100 g of resin each year (Seeley 1995).

Nectar is the energy currency of the colony and is collected both to fuel the current activity of the bees and to store for the winter and other times of dearth (Abou-Shaara 2014). Nectar is concentrated by evaporating off much of the water content, then mixed with salivary enzymes and stored as honey. If nectar is freely available, a colony will continue to collect and store as much as its labor and space resources allow. Pollen provides the protein source, as well as containing lipids and vitamins, but can only be processed by nurse bees. These young bees digest the pollen collected by foragers and convert it to a protein-rich secretion called brood food from the hypopharyngeal glands in the head and fed to other bees by trophylaxis (transfer of liquid via the proboscis). In contrast to nectar, the colony does not collect pollen indefinitely, but instead maintains a stable amount that is sufficient to buffer the colony through periods when forage is unavailable.

Water is collected for honey dilution, particularly early in the season when the colony is utilizing stored honey and pollen, and for nest cooling by evaporation. Collected in much smaller quantities, resin is mixed with saliva to form a sticky substance called propolis and used to seal cracks in the nest cavity.

The main forage substances, nectar and pollen, are collected primarily from flowers (although sugar may also be collected from fruit, honeydew, or robbing other honeybee colonies). Floral resources are transitory, characterized by a constantly varying patchwork of profitable locations that change over time. Some species of plant only produce nectar at certain times of the day, different species come into bloom at different times, and patches may be depleted and replenished over varying periods. To efficiently exploit the resources available to it, a colony must track the locations and profitability of the forage landscape as it changes over time. Patches that have ceased to be rewarding must be abandoned, additional foragers must be recruited to more rewarding patches and a scouting effort must be maintained to gather information on new forage sites. In addition, a colony must preserve a sufficient amount of stored food as a buffer during times of dearth such as bad weather or poor nectar flow, balancing this against current nutritional demands of brood and adults and available storage space and processing labor. How honeybees have evolved to respond to this foraging challenge, both at the individual and colony level, is discussed below.

## Individual Foraging Behavior

In one foraging trip, a bee collects up to 15 mg of pollen or 30 mg of nectar (or a combination of both), often requiring visits to over 100 flowers. Efficient foraging at the individual level requires the integration of learning, sensory perception, adaptable flower handling behavior, and navigation.

### Locating and Collecting Forage Resources

Honeybees rely primarily on visual and olfactory perception to locate flowers in the environment. Bees have compound eyes made up of several

thousand functional units called ommatidia, resulting in visual resolution 100 times poorer than that of the human eye (Chittka and Raine 2006). Bee color vision is determined by the presence of three different color receptors in the ommatidia (ultraviolet [UV], green, and blue), allowing bees to perceive a visible spectrum spanning 300–650 nm, encompassing UV but not red light. Green light is particularly important for motion vision and detection of small targets. The polarization pattern of light can also be detected by bees using a narrow band of photodetectors on the dorsal region of the eyes (Kraft et al. 2011). Honeybee antennae contain at least 130 olfactory receptors, resulting in highly developed odor perception.

Learning about the visual and olfactory cues that identify the most rewarding flowers plays a critical role in maximizing honeybee foraging efficiency (Menzel and Muller 1996). Bees are able to quickly learn to associate the characteristics of flowers, such as color, shape, pattern, and odor, with reward, and will preferentially visit flower types that they learn to be more rewarding. In the laboratory, it has been shown that individuals are capable of learning not just about the physical properties of these cues, but also about the relationships between them. For example, individuals can learn concepts such as “the same as,” or “above/below.” Although the extent to which such abilities are put to use in the field has not yet been fully explored, it is clear that such “nonelemental learning” abilities have potential applications in optimizing foraging efficiency. Individuals also respond to information provided inadvertently by conspecifics in the field, including the visual presence of other feeding bees, which they use to identify both rewarding inflorescences and rewarding flower species. To minimize visits to flowers that other bees have recently drained, individuals typically avoid inflorescences where they detect cuticular hydrocarbons that have been inadvertently deposited by other foragers. Finally, there is some evidence that volatiles produced by stressed conspecifics might lead bees to avoid dangerous areas where other bees have been injured, since such volatiles have been shown to induce both aversion

responses and future avoidance of contextual stimuli in laboratory settings.

Although honeybees are generalist foragers, feeding from a broad range of species, a single individual commonly prefers one species during a foraging trip (Grüter and Ratnieks 2011). This may clearly be beneficial for the plant, increasing the probability that pollen from a conspecific will be transferred to its stigma resulting in pollination, but flower constancy may also be advantageous for the bee, increasing flower handling efficiency through honing skills on a specific floral morphology, or distributing a colony's foragers across different resources. However, visiting only one species in a mixed patch of flowers may have energetic costs associated with increased flight distance between flowers, and it has been suggested that flower constancy is a constraint due to limited memory capacity for floral characteristics. Nevertheless, the behavioral flexibility of flower constancy – for example, increasing fidelity when rewards are higher – suggests an adaptive basis.

As central place foragers, individual bees must find their way home at the end of a foraging bout. Foragers use a combination of path integration, celestial compass orientation, and landmark learning to navigate to resource patches and back to the nest (De Marco and Menzel 2005). Path integration involves integrating each successive vector of travel during a flight to produce a continuously updated distance and direction from the hive. Distance is measured by the bee using optic flow, i.e., the amount of visual information that passes the eye per unit time, on the outbound flight to the resource (Si et al. 2003), while the direction is measured using celestial cues from the sun and polarized light. Bees also use memory of landmarks as a spatial reference of nest location or as checkpoints along a route.

### Communicating Forage Information

In 1946, the Austrian ethologist Karl von Frisch made a discovery that would later lead him to be awarded a Nobel Prize in Physiology or Medicine (shared with Niko Tinbergen and Konrad Lorenz): that honeybee foragers can communicate to their nestmates the location of the resource which they have visited, in order to recruit other foragers to

exploit the same resource (von Frisch 1967). This highly evolved behavior, known as the waggle dance, represents perhaps the only known example of symbolic communication in a nonprimate species. On returning to the nest with pollen, nectar, or water from a particularly profitable source, a forager navigates to a part of the comb near the entrance, the “dance floor,” where unemployed foragers are waiting for information on the day's forage. Here she performs a distinctive figure-of-eight dance on the comb, vibrating her body laterally 12–15 times per second as she walks in a straight line (the waggle phase), then ceases vibrating and veers alternately to the left or right, looping back to the start (the return phase) to repeat the waggle run (Fig. 1). This dance encodes three pieces of information about the resource: distance, direction, and quality (Couvillon 2012).

The vector (distance and direction) information is contained in the waggle phase. The distance of the resource from the nest is encoded in the length of time that the bee vibrates her body, with a linear relationship between duration and distance. Dances for locations that are very close to the hive elicit such short waggle runs that often no vibration is present, resulting in an erratic truncated dance called the round dance, now widely accepted as an extremely short waggle dance rather than a separate behavior (Gardner et al. 2008). Bees have a gravity-proprioceptive system involving sensory neurons in the neck hair plates, allowing the bee to direct her waggle run at a specific angle relative to gravity. This corresponds to the angle from the current solar azimuth at which the resource is located, measured from celestial compass information. A bee may continue dancing over sufficient time for the sun's position to have moved, rendering the original dance angle inaccurate; however, the integration of endogenous circadian clock information allows a dancer to extrapolate the current azimuth without leaving the nest, modifying her angle to track the sun's position over time.

A combination of tactile input via antennation of the dancer's abdomen and perception of directional jet air flows produced by the oscillation of the dancer's wings allow bees following the dance to determine the angle and duration in the

**Foraging by Honeybees, Fig. 1** The honeybee waggle dance. A forager returning from a profitable resource such as a flower patch informs her nestmates of the location of the resource by performing a distinctive figure-of-eight dance on the comb (*left*). Two pieces of information are encoded in the dance (*right*): (1) the angle from the solar

azimuth, encoded in the angle of the waggle run with respect to gravity; and (2) the distance from the nest, encoded in the length of time for which the bee vibrates her body. This forms a vector allowing unemployed foragers following the dance to locate the resource

darkness of the hive (Gil and De Marco 2010; Michelsen 2003). These two pieces of information form a vector that is theoretically sufficient for nestmates to locate the resource. However, there is considerable variation between different runs within a single dance, meaning that the dance does not signify a precise location. Could this error be adaptive? Floral resources rarely consist of a single point in space, and researchers have theorized that the error has evolved to optimally spread foragers across large patches of flowers. Accordingly, angular variation decreases with increasing communicated distance, consistent with recruits being spread across even-sized patches at near and far distances. Yet there is also considerable evidence to the contrary, suggesting that dance angle variation is driven by biophysical constraints: for example, error is reduced when dancers have a direct view of the sun, when dancing parallel to gravity or when return phases are longer (Preece and Beekman 2014). To minimize the effects of this error, it appears dance followers take an average of several

runs, with recruits that follow more runs locating the site more accurately.

Not all foraging resources are of equal quality: nectar concentration and volume, distance from the nest, floral density, and risk of predation or competition all contribute to the profitability of a resource (Abbott and Dukas 2009). The third piece of information encoded in the dance concerns resource quality, primarily in the form of the number of waggle runs performed. Bees may perform between 1 and 100 runs within a single dance, with a linear relationship between number of runs and resource quality. The rate of waggle runs per unit time, modified by altering the duration of the return phase, is also correlated with quality. A forager's measure of profitability is based on two sets of variables: features of the resource itself and the current forage supply and demand of the colony. For nectar sources, resource variables include sugar concentration; while all bees show a linear relationship (up to the point where viscosity limits profitability) between runs and sugar concentration, individual

assessment varies widely between bees, reflected in differences in the slope of the relationship and the concentration threshold that elicits dancing. Sugar concentration is combined with the energetic cost of the flight (related to distance, but not measured using optic flow) to calculate the energy efficiency of exploiting a resource and it is this in addition to risk that informs a bee's assessment of the objective quality of a resource.

In contrast to nectar, it is likely that bees cannot assess the protein content of pollen (Beekman et al. 2016). Assessment of relative profitability in the context of current overall forage influx into the colony and processing capacity is discussed below. Combining these variables results in a final integrated assessment of quality encoded in the run number and intensity. However, unlike the vector information, this is not directly perceived by dance followers, who only follow a small proportion of the runs of any dance. Instead, this forms part of the elegant system of feedback loops regulating forage intake at the colony level described below.

### Colony-Level Foraging Behavior

We have seen that the individual forager possesses a suite of complex behavioral traits that allow her to efficiently locate flower patches, collect resources, and communicate their location on return to the nest. How are these individual endeavors integrated at the colony level, to spread labor across the foraging landscape, tightly control the influx of resources and regulate the balance between collection and processing of food? Like the human body, a honeybee colony must regulate its energy intake and expenditure, maintaining a complex array of homeostatic processes that depend upon extensive information flow between its units, the individual bees. No single individual or group possesses global information about all the processes occurring in the colony. Rather, each individual responds to local information according to a set of simple rules, resulting in a self-organized system that is capable of responding flexibly to environmental conditions and making adaptive decisions in its own

right. Information flow in the colony consists of a combination of signals (behaviors that have evolved specifically to convey information) and cues (provided inadvertently, as a byproduct of other behavior) (Seeley 1998). One example of a signal, the waggle dance, has already been discussed; in the following section, we present a further array of signals and cues involved in the regulation of foraging at the colony level.

### Spreading Labor Across the Foraging Landscape

At its strongest, a honeybee colony may contain up to 60,000 workers. This labor market must be effectively distributed across the major behavioral roles – cleaners, nurses, food storers, and foragers – and even across subdivisions within those groups, such as pollen or nectar foraging, scouting, or dance following. The proportion of workers involved in each task must be balanced with the supply and demand of brood and forage, and coordinated with other roles; it does not work to have large numbers of successful nectar foragers returning if there are insufficient food storers to receive their loads. At the highest level, behavioral tasks are allocated by age: newly emerged bees clean cells, the second youngest care for brood, middle-aged bees process food and perform other in-nest tasks and the oldest bees forage. This age polyethism potentially maximizes worker longevity, with the task involving the highest associated mortality, foraging, allocated to bees close to the end of their natural lifespans. The age of transition is flexible and can respond to changes in colony requirements. Within the forager caste, an individual's propensity to collect pollen, nectar, or water is associated with sensitivity to sucrose; bees with low, medium, and high sucrose response thresholds preferentially forage for water, pollen, and nectar respectively. This variation is thought to be adaptive at the colony level, facilitating division of labor.

At any one time, around a quarter of the colony workforce are foragers. Those not currently employed in exploiting a resource, due to the abandonment of a no longer rewarding patch or just beginning their foraging career, may be

allocated to a patch in a number of ways. A small proportion of foragers will be scouts, exploring the environment in search of novel food sources. The remaining foragers may use memory of previously visited patches, or social information to locate resources. Social information about foraging locations comes in the form of waggle dances or via olfactory information from floral odor carried on dancers' bodies or in nectar samples transferred to followers (trophallaxis). At any time on the dance floor, several dancers may be advertising multiple different locations. How does a forager choose which location to visit? As previously described, the dancer encodes the profitability of the resource in the number of waggle runs performed. One solution would be for a follower to survey many of the dances and select the one communicating the highest quality. However, such a system would not only require extensive dance sampling effort on the part of dance followers, but also necessitate measurement and comparison of the number of runs that each dancer performs. Instead, a much simpler self-organized system has evolved to achieve the same end, based on each worker responding to a small amount of local information rather than collecting global information. A dance follower has no perception of the quality encoded in the dance, and thus she may well select and follow a dance not advertising the most profitable site available. However, because dances for higher quality sites contain more runs, the number of bees that encounter these dances is higher. As such, the number of recruits to a resource is proportional to the number of waggle runs performed for it. In addition, more profitable resources are more likely to elicit dances in the first place. This ensures an appropriate distribution of foragers across sites, relative to their quality, and allows the colony to rapidly track changes in profitability.

A surprisingly low proportion of dance followers visit the advertised site. The location encoded in the waggle dance (a signal) is not the only piece of information provided by dancing bees, and the floral odor carried by dancers (a cue) may take precedence over the location information conveyed by the dance (Grüter and Farina 2009). If the odor is from a flower species a

follower has experience with, this can reactivate the memory of a previously visited forage patch, creating a conflict between personal memory and social information about forage locations encoded in the dance (Grüter et al. 2008). There is evidence that in this scenario bees preferentially rely upon their own location memories, but increase their use of waggle dance information when those sites become unrewarding. As foragers age, they rely less on waggle dance information and more on private memory. Unemployed foragers may also follow a dance for confirmation of the continued profitability of a previously visited site. In practice, only 12–25% of dances are followed for the discovery of new sites, with the remaining associated with reactivation to known resources (Biesmeijer and Seeley 2005).

### Regulating Nectar Influx

Collection of resources must be coordinated with the colony's current requirements. Returning nectar foragers must decide whether to recruit additional foragers to a patch, given the current availability of other sources. Rather than collecting direct, global information about the entire colony's nectar influx, returning foragers use an indirect cue in the form of the time it takes to unload their nectar load. If nectar influx is currently low, there will be several unemployed food-storer bees waiting to receive nectar, so unloading time will be short. If nectar influx is high, a returning forager may have to queue to unload. The precision of this measurement is increased by making multiple transfers of portions of the load; the average unloading delay informs the forager about the colony's nectar influx. Although her objective assessment of the quality (sugar concentration, distance, and risk) of the resource does not change, this information about nectar influx alters the quality threshold that elicits a dance and the intercept of the relationship between quality and number of runs. Therefore, a low-quality resource that would elicit many waggle runs during a time of dearth may not elicit any dancing at all during peak nectar flow.

In addition to the waggle dance, several other movement signals have evolved to regulate the balance between nectar collection and processing.

Unloading delay is also used by returning foragers to perceive a need for increased food processing effort. A long delay increases the probability that the returning forager will subsequently perform a “tremble dance,” which stimulates nest bees to become food-storers and inhibits waggle dances in other returning foragers (Biesmeijer 2003b). A bee shaking a nestmate by grasping her with her legs and vibrating her body forms a more general, context-dependent signal to encourage reassessment of current activity (Biesmeijer 2003a). An inhibitory signal, the stop signal, is also now known to be used by foragers and dance followers to interrupt dancers advertising a site known to be associated with danger from predation or competitive aggression or to be no longer rewarding (Nieh 2010).

### Homeostatic Control of Pollen Stores

As discussed above, the only limits to the amount of nectar a honeybee colony extracts from its environment are the labor available to collect and process it and the space available for storage. In contrast, a colony maintains a limited stable pollen store that requires precise homeostatic control (Schmickl and Crailsheim 2004). Thus, instead of being driven primarily by supply, pollen foraging is also driven by demand. Pollen demand changes with the amount of brood present and supply changes with the foraging conditions; regulation needs to integrate both these variables. How pollen stores are homeostatically controlled has been subject to considerable debate and research effort, with two main theories posited: (1) the direct, independent hypothesis, and (2) the brood food hypothesis.

The direct, independent hypothesis suggests that the global status of pollen supply and demand are measured directly by returning foragers. Quantity of stored pollen (supply) may be measured by the time taken to find an empty cell; unlike nectar, pollen is deposited directly into cells by foragers. Amount of brood (pollen demand) may be measured by brood pheromone levels in the nest, which may be either an evolved signal or an incidental cue. According to this theory, foragers integrate these pieces of

information to assess the need to collect pollen. Some evidence in support of this exists: brood pheromone has been shown to affect pollen foraging activity and returning pollen foragers perform cell inspections (Dreller et al. 1999). The alternative theory suggests that an indirect cue – the protein content of the hypopharyngeal secretions (“brood food”) fed by nurse bees to all workers – gives information on the combined pollen supply and demand. In times of protein scarcity, either due to increased brood or reduced pollen stores, low protein content in the brood food fed to foragers would stimulate increased pollen foraging. Research has shown that separating foragers from the pollen stores with a screen does not disrupt pollen store homeostasis (Camazine 1993), suggesting that direct contact with stores is not required, and an inhibitory effect of trophallaxis on pollen foragers has also been found (Camazine et al. 1998). However, experiments using a protease inhibitor to artificially lower brood food protein content have found no evidence for the brood food hypothesis (Sagili and Pankiw 2007). The two hypotheses are not mutually exclusive, and it is likely that a combination of direct and indirect cues are involved in regulation of pollen storage.

### Conclusion

In any animal species, foraging behavior is under intense selection pressure. The ability of an individual to successfully extract energy and nutrition from its environment while minimizing hazards and metabolic costs is a strong driver of fitness. The honeybee is no exception: natural selection has shaped individual foraging behavior such that a bee can locate flower patches, efficiently collect nectar and pollen and remember the locations and characteristics of profitable resources. However, the honeybee differs from most other taxa in that selection has also acted strongly upon foraging behavior at another level of biological organization: the colony. The behavior of the “superorganism” has evolved such that the colony acts as a static reproductive unit from which

individual parts can be deployed to collect resources from its surroundings. As such, selection has favored maximizing the energy balance and nutritional regulation of the colony as a whole. Intricate networks of information flow via communication signals and cues coupled with a suite of behavioral rules at the individual level in response to local information results in a highly complex self-organized foraging system. In this way, the honeybee colony provides an intriguing comparative model for nutritional regulation and sensory perception in analogous self-organized systems such as the human body, on a macroscopic scale.

## Forced Copulation

Rachel Schepke and Todd K. Shackelford  
Department of Psychology, Oakland University,

## Synonyms

[Rape](#); [Sexual coercion](#)

## Definitions

Forced copulation occurs when a male forces sexual intercourse on an apparently resistant female. Gang rape occurs when two or more males force copulation on a female at the same time. Sexual coercion refers to unwanted copulations within an established pair-bond. Extra-pair copulations refer to matings that occur outside of a pair-bond.

## Introduction

Forced copulation occurs in many species, including birds, insects, and mammals – including humans (Baker 2020/1996; Baker and Bellis 2014/1995; Goetz and Shackelford 2006; McKinney et al. 1983). Gang rape also occurs in many species, including birds, butterflies, and humans (Baker 2020/1996; Baker and Bellis 2014/1995; McKinney et al. 1983). Rates of forced copulation typically increase during times of stress, such as during warfare in humans (Baker and Bellis 2014/1995). Forced copulation may have evolved because it increased the coercive male’s reproductive success (Baker 2020/1996; Baker and Bellis 2014/1995; Cheng

et al. 1982; Goetz and Shackelford 2006; McKinney et al. 1983), or forced copulation may be a by-product of male adaptations that motivate desire for sexual variety and the use of aggression to secure desired resources (Goetz and Shackelford 2006).

### Tactics Used in Forced Copulation

Males attempt to force females to copulate using various tactics such as chasing after or confronting the female. For example, in many species of birds, males chase the female before mounting her, apparently against her will (Cheng et al. 1982). Once the male has the female in possession, he grasps part of the female's feathers with his beak and places his wings on both sides of the female's body to prevent her from escaping (McKinney et al. 1983). Male minks that engage in forced copulation initiate physical fighting with the female because pre-copulatory fighting may induce ovulation, increasing the likelihood of conception (Baker and Bellis 2014/1995). In several species of birds, males are more likely to pursue forced copulation with more fertile females that recently produced a healthy clutch with another male. The male perpetrator typically attacks the female in the mornings, shortly after she lays her eggs and when she is most fertile, and early in the breeding season (Baker 2020/1996; Cheng et al. 1982).

In some species, males may compensate for smaller-than-average body size by utilizing specialized body parts that aid in trapping the female for copulation. Male scorpion flies, for example, use a special hook on their wings to grip and secure the female and then force copulation (Baker 2020/1996). In some species, including ducks, birds, and butterflies, males engage in gang rape when they are unsuccessful at mating without the assistance of other males. Gang rape involves males coordinating different roles and rotating for sexual access to the female. For example, some male ducks chase the female, other males guard her from escaping, and one male forces copulation with the female (Baker 2020/1996).

### Reasons for Forced Copulation

Males of some species apparently force copulation as a reproductive strategy. In many species, most males that engage in forced copulation do not fail at consensual copulations and neither are they disadvantaged; rather, these males pursue forced copulation and gang rape as additional copulations and select and pursue females that are attractive and at peak fertility (Baker 2020/1996; Baker and Bellis 2014/1995). However, males in other species, such as in scorpion flies, force copulation as a reproductive strategy to compensate for disadvantages such as small size or failed mating success (Baker and Bellis 2014/1995). Reproductively disadvantaged males are more likely to engage in gang rape because the female is less likely to escape than if the male were to attempt to force copulation on his own (Baker and Bellis 2014/1995).

Males are more likely to force copulation via sexual coercion when infidelity occurs or the male suspects his long-term partner's infidelity. Sexual coercion occurs in many socially monogamous species, such as humans, birds, and a few mammals, in which males force copulation with their regular partner in response to threatened paternity. Females that engage in extra-pair copulations promote sperm competition among the males they mate with, thereby threatening their regular partner's paternity certainty – the degree to which a male is certain that his partner's offspring are genetically his own. Sperm competition occurs when more than one male's sperm is present in a female's reproductive tract and compete to fertilize available ova (Goetz and Shackelford 2006). Thus, a mated human male may force his partner to copulate if he suspects an extra-pair copulation occurred to increase his paternity certainty, punish his partner, or prevent future infidelities (Baker 2020/1996; Baker and Bellis 2014/1995; Goetz and Shackelford 2006).

### Costs and Benefits for the Perpetrator

Various types of forced copulation, such as gang rape and sexual coercion, involve sexual conflict

and entail costs. For instance, males who force females to copulate risk being injured or killed by the female if she resists (Baker 2020/1996). Furthermore, the male's safety is threatened by other individuals who discover the female is in danger and attack the perpetrator (Baker 2020/1996; McKinney et al. 1983). Regarding gang rape, males risk losing the competition to inseminate and fertilize the female (Baker 2020/1996; Baker and Bellis 2014/1995; McKinney et al. 1983).

Although forced copulation can be a reproductive strategy, males may fail to reproduce using this tactic. On the other hand, males may successfully produce offspring by forcing copulation. Females may be more likely to conceive via forced copulation than consensual copulation, and considering males typically target victims of higher reproductive value, offspring are more likely to inherit "good" genes, survive, and be successful at mating, thus benefiting the reproductive success of the male that forced copulation (Baker 2020/1996; Baker and Bellis 2014/1995; Cheng et al. 1982; McKinney et al. 1983). Considering males often abandon the female after forcing copulation, males who successfully reproduce via this strategy incur the benefits of not having to invest time or resources in the female and her offspring (Baker and Bellis 2014/1995), thus allowing the male more opportunities to increase his reproductive success.

### Costs and Benefits for the Victim

Female victims of forced copulation are at risk for being injured or killed by the perpetrator (Baker 2020/1996; Baker and Bellis 2014/1995) and human victims often suffer negative psychological and physical health outcomes (Goetz and Shackelford 2006). Females may incur the costs of rearing resulting offspring with no paternal investment if the perpetrator abandons her after forcing copulation (Baker 2020/1996), thereby reducing her reproductive success. A female's reproductive success may also be hindered if her offspring inherit low-quality genes (Baker 2020/1996), because the offspring may be less likely to survive or be less successful at producing

offspring and thereby fail to transmit the mother's genes. However, females also may benefit reproductively by producing offspring sired by forced copulation, because these offspring may also be successful at transmitting genes through forced copulation (Baker and Bellis 2014/1995).

### Conclusion

Among many species, forced copulation by the male is not uncommon and may be used as a reproductive strategy. Tactics for successfully forcing copulation include chasing, holding down, and harming the female. Males that force copulation may be disadvantaged for success in mating, sperm competition, or infidelity. Male perpetrators risk being physically harmed and not producing offspring by forcing copulation but may sometimes be reproductively successful by producing offspring without the costs of investing time and resources in the female or resulting offspring. Female victims are at risk of harm by being forced into copulation, and then abandoned, but may benefit by producing offspring who are successful at transmitting their genes.

## Framing Effects

Stephanie M. Carpenter  
Department of Psychology, University of  
Wisconsin-Madison, Madison, WI, USA

### Introduction to Framing Effects

The way that information is presented systematically changes perceptions of and reactions to that information, even when the details remain objectively equivalent. These perceptual shifts subsequently alter judgments and decisions. Traditional

models of decision-making suggest that people make rational choices based on showing consistency and coherence in their decision making (cf. Kahneman and Tversky, *Journal of the Econometric Society*, 47(2), 263–291, 1979; Tversky and Kahneman, *Science*, 211(4481), 453–458, 1981). In other words, rational models propose that people will select the same choice option across different contexts. However, a vast literature has shown that *framing effects*, where different message frames change and even reverse people's judgments and decisions about equivalent choice problems, aid in our understanding of the decision process (cf. Kahneman and Tversky, *Econometrica: Journal of the Econometric Society*, 47(2), 263–291, 1979; Kahneman and Tversky, *American Psychologist*, 39(4), 341–350, 1984; Levin et al., *Organizational Behavior and Human Decision Processes*, 76(2), 149–188, 1998; Tversky and Kahneman, *Science*, 211(4481), 453–458, 1981).

Much of the literature on framing effects has dealt specifically with people's evaluations of risky choice options (e.g., gambles) and how differences in the framing of these options influence the way that risk is evaluated in decision-making. Risky choice problems require the decision maker to choose between either a sure outcome (i.e., certain to win or lose a specific amount) or a risky gamble where the outcome is uncertain (i.e., there is a chance you could either win or lose). When faced with a risky choice context, individuals evaluate the available information relative to a reference point. Individuals systematically become more risk-averse or risk-seeking based on whether the decision problem is framed as a gain or loss, relative to that reference point. However, other judgment and choice contexts that do not necessarily involve risk are also susceptible to the influence of framing (cf. Levin et al., *Organizational Behavior and Human Decision Processes*, 76(2), 149–188, 1998).

This entry outlines some of the essential literature on framing effects in judgment and decision-making. In doing so, it explores how framing influences risky decisions, explores the influence of emotions on framing effects, examines the neural correlates of framing effects and how framing effects have been demonstrated in nonhuman

animals, addresses framing beyond risky choice problems, and discusses real-world situations in which people may be susceptible to framing effects.

## Framing Effects in Risky Choice: Gain and Loss Frames

Framing effects have traditionally been studied in the context of gain and loss messages. A message is believed to be in a “gain frame” when an outcome is portrayed in terms of benefits (e.g., number of lives *saved*), whereas a “loss frame” describes when that outcome is portrayed in terms of costs (e.g., number of lives *lost*). For example, in a traditional risk task known as the Asian disease problem (cf. Kahneman and Tversky 1979, 1984; Tversky and Kahneman 1981), people are presented with the following scenario:

Imagine that the U.S. is preparing for the outbreak of an unusual Asian disease, which is expected to kill 600 people. Two alternative programs to combat the disease have been proposed. Assume that the exact scientific estimates of the consequences of the programs are as follows:

Half of subjects are presented with a *gain frame*:

- If Program A is adopted, 200 people will be saved. (*Sure gain*)
- If Program B is adopted, there is a one-third probability that 600 people will be saved and a two-thirds probability that no people will be saved. (*Risky gamble*)

Half of subjects are presented with a *loss frame*:

- If Program C is adopted, 400 people will die. (*Sure loss*)
- If Program D is adopted, there is a one-third probability that nobody will die and a two-thirds probability that 600 people will die. (*Risky gamble*)

Note that the proportion of lives saved versus lives lost is equivalent in both the gain and loss frame scenarios (i.e., the expected value of selecting either option is the same). However, people who view the Asian disease problem in the “gain frame” become more risk averse because they focus on how many lives will be saved (Kahneman and Tversky 1984). In other words, viewing the problem in a gain frame increases the likelihood that the decision-maker will select Program A, where 200 people will be saved for

sure. On the other hand, individuals who view this problem in the “loss frame” tend to focus on the sure losses incurred and consequently become more risk seeking. That is, the decision-maker in the loss frame is more likely to select the risky gamble outlined in Program D, where there is a 2/3 probability that nobody will die but also a 1/3 probability that all 600 people will die (Kahneman and Tversky 1984).

This choice reversal, termed the “reflection effect,” is also observed in simple numeric gambles involving risk (cf. Kahneman and Tversky 1979). These seemingly counterintuitive effects arise because people exposed to a loss frame are more willing to gamble in order to avoid a sure loss (i.e., become more risk seeking) (cf. Kahneman and Tversky 1979). This also highlights the concept of loss aversion, whereby people tend to prefer avoiding a loss over acquiring equivalent gains. Consequently, in a gain frame, people will avoid the gamble to ensure that they gain something (i.e., become more risk averse).

## Emotion and Framing Effects

Emotion interplays with decision-making to influence behavior in a variety of ways (cf. Lerner et al. 2015), and several behavioral studies have shown that emotions modulate framing effects. Research examining the relationship between affective valence (i.e., positive or negative feelings) and framing effects suggests that inducing positive feeling states reduces loss aversion, and this ameliorates framing effects such that people no longer change their choice based on whether the decision problem is framed as a loss or a gain (Cassotti et al. 2012).

Other work examining discrete emotions suggests that distress (Druckman and McDermott 2008) and fear (Lecheler et al. 2013) increase framing effects, whereas anger decreases framing effects (Druckman and McDermott 2008; Lecheler et al. 2013). Contentment has also been found to reduce framing effects (Lecheler et al. 2013), and enthusiasm produces mixed results where for some scenarios it decreases framing

effects (Druckman and McDermott 2008; Lecheler et al. 2013) and for others it does not (Druckman and McDermott 2008). Thus, to gain a more complete understanding of the interplay between emotion and framing effects, it is critical to study not only positive or negative valence but to also investigate how discrete emotions differentially influence people's reactions to message frames.

Future behavioral examinations will be critical as discrete emotions often vary based on perceptions of situational certainty. For example, fear is marked by low situational certainty appraisals, and anger is marked by high situational certainty appraisals (cf. Lerner and Keltner 2001). Seeing a snake can make people feel uncertain about the safety in the situation and thus lead them to experience fear. On the other hand, when encountering a rude person, an individual may feel certain that the rude person's behavior was unjust and consequently experience anger. The "cognitive appraisal" of certainty is especially useful in the assessment of risk (cf. Lerner and Keltner 2001), as fear has been shown to systematically increase risk aversion (e.g., run away from the snake) and anger to systematically increase risk-seeking behavior (e.g., yell at the rude person). Examinations of the influence of emotional states on the framing of risky choice options warrant additional research.

## Neural Correlates of Framing Effects

A growing literature within the field of decision neuroscience has sought to uncover the neural mechanisms underlying framing effects. Consistent with behavioral findings, neural regions associated with emotion and reinforcement learning have also been implicated in framing effects (De Martino et al. 2010; Deppe et al. 2007; Windmann et al. 2006; Zheng et al. 2010). For instance, De Martino and colleagues (2006) found that framing effects were associated with amygdala activity. The amygdala is a region of the brain commonly associated with salience, value-related prediction and learning, and the processing of emotional information (cf. De Martino et al.

2006), and so this finding supports a link between the framing of risky choices and neural systems related to emotion. However, more recently, a study found that lesions to the bilateral amygdala did not significantly alter framing effect behavior (Talmi et al. 2012). These inconsistent findings suggest that the relationship between amygdala activation and framing effects warrants further exploration.

Greater activity of the orbital and medial prefrontal cortex (OMPFC), associated with reward processing and the integration of emotional information into decisions, was linked to lower susceptibility to framing effects (De Martino et al. 2010). Further, activation of the ventral medial prefrontal cortex (vmPFC), another region associated with the use of emotion in decision behavior, was correlated with people's susceptibility to message frames (Deppe et al. 2005). A similar pattern was found in activation of the anterior cingulate cortex (ACC), a neural region associated with the processing of information about positive and negative reinforcements (Deppe et al. 2007). Deppe et al. (2007) revealed that greater activation in the anterior cingulate cortex (ACC) predicted increased susceptibility to framing effects, suggesting a critical role for reinforcement learning in our understanding of framing effect biases. Taken together, these findings further support the importance of emotion systems in the processing of risky choice frames.

Other work has suggested that framing effects rely on a trade-off between the cognitive effort required to calculate expected values and the affect (e.g., emotion) associated with a particular choice option (Gonzalez et al. 2005). Results indicate that the cognitive effort required for participants to select a sure gain (e.g., in the Asian Disease problem described above, the 200 lives saved for sure) was less than for a risky gain (e.g., 1/3 chance of saving 600 lives, 2/3 chance of saving 0). However, the effort expenditures were equivalent for sure losses (e.g., 400 lives lost for sure) and risky losses (e.g., 1/3 chance nobody will die, 2/3 chance 600 will die). Gonzalez et al. (2005) further described neural associations between regions of the prefrontal and parietal cortices while people were making decisions

involving framing, which are brain regions typically involved in working memory and imagery processing.

Windmann et al. (2006) also examined the link between the medial and lateral orbitofrontal cortex (OFC) and sensitivity to information frames. Activation of the medial OFC has been associated with the detection of positive and negative affective valence, whereas activation of the lateral OFC is believed to represent the extent to which outcomes change (e.g., a gamble where lives are either saved or lost) or stay the same (e.g., lives are always lost or always gained). The lateral OFC was indeed found to be sensitive to the steadiness of outcomes and showed effects above and beyond activation of the medial OFC. These data indicate that both the processing of valence and outcome steadiness are important to our understanding of the neural mechanisms underlying framing effects (Windmann et al. 2006).

### **Risky Choice Framing Effects in Nonhuman Animals**

One consideration in understanding framing effects is whether the observed behaviors are specific to humans. For instance, it could be that cultural influences have led to an increased sensitivity to framing effects. It is, however, also plausible that contextually sensitive framing effect biases have more of a biological basis. One way to address this problem is to examine whether similar behaviors exist in nonhuman animals. Initial investigations suggest that framing effects are not limited to humans and can be observed in nonhuman primates (i.e., capuchin monkeys; Chen et al. 2006; Lakshminarayanan et al. 2008, 2011) and in birds (i.e., starlings; Marsh and Kacelnik 2002).

For example, in a recent demonstration, Lakshminarayanan et al. (2011) presented capuchin monkeys with tokens that could be traded for apple slices. Monkeys in the loss frame condition were presented with three apple slices as a reference point. Experimenter 1 always deducted one apple slice when given a token (i.e., sure loss), whereas Experimenter 2 either deducted two

apple slices or deducted no apple slices, at an equal rate (i.e., risky loss). Monkeys in the loss frame condition showed a preference for giving a token to Experimenter 2 (the risky loss), indicating risk-seeking decision behavior that parallels that of humans in a loss frame condition. In the gain frame condition, monkeys were presented with one apple slice as the reference point. Experimenter 1 always added one apple slice when given a token (i.e., sure gain), and Experimenter 2 either added two apple slices or added no apple slices, at an equal rate (i.e., risky gain). As with humans, monkeys in the gain frame showed a preference for giving the token to Experimenter 1 (the sure gain), indicating risk-averse decision behavior for gains.

Framing effects have also been observed in research on European starlings. Marsh and Kacelnik (2002) demonstrated that training birds to peck a symbol in exchange for food led to more risk-seeking behavior in the loss treatment. The starlings were more likely to peck the risky loss symbol that resulted in a loss of either one or five (out of a total of seven) pellets at an equal rate, over pecking the sure loss symbol where three (out of seven) pellets were always lost. Like the research on capuchin monkeys described earlier, the loss frame results parallel that of human choice behavior. In the gain frame treatment, however, where pecking one symbol always led to receiving three pellets (sure gain) and pecking an alternative symbol led to a gamble of receiving either one or five pellets, with equal chance (risky gain), there were no significant differences in the amount that starlings pecked one symbol over the other. Thus, unlike humans and capuchin monkeys, European starlings faced with a gain treatment were not more risk seeking.

Despite the lack of strong evidence for framing effects in the gain condition, starlings' response in the loss frame condition still suggests that a sensitivity to loss is present across species. Thus, changes in risk preference, particularly for losses, are indeed observable in nonhuman animals. Future mechanistic accounts of framing effects would benefit from continuing to explore this and other decision biases using both animal and human models.

## Framing Effects Beyond Risky Choices

While framing is critical to decisions involving risky choice probabilities, other information in a decision problem is also susceptible to framing effects. Levin et al. (1998) presented a taxonomy of framing manipulations organized into three distinct categories: risky choice framing, attribute framing, and goal framing.

**Risky Choice Framing.** As described throughout this entry, risky choice framing involves the consideration of choice options that differ in their level of risk. Risky choices include the comparison of simple monetary gambles or other risk scenarios, like the Asian disease problem, where framing the message to highlight gains or losses influences how risk averse or risk seeking the individual becomes.

**Attribute Framing.** In this type of framing, components of a decision (i.e., an attribute or feature) become the focus of the frame rather than the level of risk. For example, Levin and Gaeth (1988) showed that framing the quality of a ground beef as 75% lean (positive frame) versus 25% fat (negative frame) changed how positively or negatively people evaluated the beef on the attribute of its quality. Attribute framing highlights specific attributes as relatively “good” or “bad” and can be applied either to risky or to non-risky attributes in a decision problem (Levin et al. 1998).

**Goal Framing.** In this category, the goal of an action or behavior becomes the focus of the frame, and goal framing is commonly used in persuasion attempts. Goal framing becomes most relevant in contexts where the persuader aims to encourage people to engage in a behavior. The message of the goal can either take a positive frame and focus on the benefit of the action (e.g., women who do regular breast self-examinations (BSEs) have an increased chance of finding a tumor early; cf. Meyerowitz and Chaiken 1987) or take a negative frame and focus on its potential to prevent or avoid a loss (e.g., women who fail to do regular breast self-examinations (BSEs) have a decreased chance of finding a tumor early). Meyerowitz and Chaiken (1987) found that the negative goal frame is often more influential than the positive goal

frame in critical contexts, such as those often encountered when making healthcare decisions.

All three types of framing effects systematically influence decision behavior. Goal and attribute framing are distinguishable in that goal framing typically focuses on achieving the action or behavior (e.g., BSE), whereas in attribute framing, the attribute is framed as either good (75% lean) or bad (25% fat).

It should be noted, however, that framing effects have been shown to be more reliable for risky choice and attribute framing than for goal framing (Levin et al. 2002). Levin et al. (2002) suggest a plausible explanation that different processes underlie goal framing, such that goal frames will be less effective in cases where the goal is less critical or self-relevant to the decision maker.

## Framing Effects in Other Translational Settings

Framing effects also lead to differences in how people navigate decisions involving healthcare, politics, and financial decisions. Within the framing of risky medical decisions, gain-framed persuasion appeals are more effective when the message targets behaviors that prevent the onset of some disease, whereas loss-framed appeals are more effective when targeting behaviors that detect the presence of an existing disease (Rothman et al. 2006). Thus, the framing of risky health information critically depends on whether the decision is framed as being about prevention or detection of a health condition.

Politics are another critical choice domain in which a variety of message frames are used. Framing effects in political settings are important because the way a message is framed can influence long-term political candidate and policy voting decisions. In an investigation of the difference between message framing and persuasion in mass political communication, Nelson et al. (2001) provided empirical evidence of how framing and persuasion messages are differentially effective, depending on whether the goal is to activate or alter a person's belief system. Specifically,

framing was shown to function mostly by activating pre-existing cognitions and beliefs. Persuasion appeals, on the other hand, seek to add to or change something about a person's beliefs. Distinctions such as these are important to our understanding of how message framing affects decisions above and beyond basic persuasion attempts.

Choice diversification (i.e., diversifying across several choice options) in financial decision-making is also susceptible to the effects of framing. For example, Fox et al. (2005) examined the implications of choice diversification using a framing technique called "partition dependence." In partition dependence, if the choice/option sets are subjectively partitioned in different ways, then choices and allocations will vary systematically with those partitions. For example, when an individual donates to a charity that is grouped (i.e., partitioned) by domestic and international, they might diversify by allocating half of their charitable contributions based on this grouping. If, however, these same charities are grouped by local, national, and international, a person who allocates their money evenly across the three groups will consequently donate more to domestic than to international causes. Fox et al. (2005) found that partition dependence occurs across domains, particularly when decision-makers lack expertise or strong intrinsic preferences. These partition effects are observed even in competitive prediction markets (i.e., financial, sports, weather), including when informed traders are incentivized to bet on their beliefs about events (Sonnemann et al. 2013).

## Conclusion

In sum, framing effects systematically influence judgments and decisions across a variety of contexts. The findings described in this entry, although not comprehensive, are meant to provide an overview of research on framing effects within the literature. Framing effects have consequences not only for hypothetical monetary gambles and risky choice scenarios but can have very real outcomes for how people make judgments and

decisions in daily life. Future research should continue to explore when and how framing effects influence behavior and provide more evidence for how translational contexts like healthcare and political decisions are influenced by message framing.

## Frank Ambrose Beach

Peter H. Klopfer

Department of Biology, Duke University,  
Durham, NS, USA

Frank Ambrose Beach, Jr., was the doyen of modern behavioral endocrinology, the study of the influence of hormones on behavior. His text, “Hormones and Behavior,” published in 1948, is the seminal volume on the subject and to this day remains a major source of information. While research on hormones and their effects received a significant impetus early in the twentieth century, especially with Rowan’s studies on the induction of migratory behavior in birds (which, of course, had been anticipated by Aristotle; Rowan 1931, *The Riddle of Migration*, Williams and Wilkins Press), it was Beach more than any other scientist of his generation who brought the discipline into full flower.

Beach was the son of Frank Ambrose Beach and Berthe Robinson Beach, the first of three offspring. His birthday was on 13 April 1911. His education was at Emporia State University, in Kansas, his home state, and Antioch College,

from which he graduated in 1932. With several stints as teacher behind him, he eventually completed a doctorate at the University of Chicago and then spent a year with Carl Lashley before joining the staff of the American Museum of Natural History in 1937. Almost a decade later, he moved from New York and the American Museum to Yale. Yet another decade later, in 1957, he spent a year at Stanford's Center for Advanced Study, moving from there to the University of California at Berkeley, where he remained until his death. He married three times and, with his second wife, raised two children. (His biography is fully detailed in Donald Dewsbury's "Portraits of Pioneers in Psychology.")

Beach clearly confounded many who encountered him. He could appear in a neighborhood bar as a blue-collar laborer or enthrall a group of distinguished Cambridge dons with his incisive discourses. As a young and inexperienced graduate student, I first met him when my professor insisted I cross town and present my thesis plans to Professor Beach. I timidly knocked on Beach's office door and was then tempted to flee when a booming voice ordered me to hurry on in. It was a warm spring day in New Haven, and Beach was casually dressed, lounging in his reclining chair with a can of cheap beer in his hand. The walls of his office were adorned with photos of the penises of various animals, most of them erect. Except for Beach's broad smile and gentle assurances, I would never have had the nerve to speak, but, with his encouragement, I outlined my plans. He quickly reached for the phone, explaining as he did so, that he wanted his student, Julian Jaynes (who later, as a professor at Princeton, was the author of "The Bicameral Mind"), to participate in our discussion. Julian soon appeared and we adjourned to a local pizza parlor for food, beer, and friendly discourse. This was a pattern which repeated itself in one form or another for decades: Beach was the consummate mentor, though also exceedingly demanding of precision and clarity.

As his long list of publications reveals, he had an exceptional breadth of interests and knowledge, a critical approach to empirical science, and deep understanding of the philosophical implications of his work. More than any other

biologist or psychologist of the 1950s and 1960s (except perhaps for Dan Lehrman at Rutgers), he countered the deterministic position of the European ethologists as represented by Konrad Lorenz (and cf. Klopfer 1994). His puckish humor is also evident in much of his writing, for example, in "The Snark is a Boojum," an argument against genetic determinism.

Beach died in Berkeley on 15 June 1988. A biographical memoir by Donald Dewsbury provides a more detailed picture of his life (Dewsbury 1998).

Dewsbury also provides a list of his more important publications, to wit:

## Frans de Waal

Ann Weaver  
Good-natured Statistics Consulting,  
St Petersburg, FL, USA

Contemporary students of animal cognition move fluidly through doorways to fascinating capabilities – peacemaking, justice, fairness, morality, and empathy – to name just a few. So unimpeded is their progress that few may fully realize how briefly these doors have been open. They may not fully realize how much work and courage it took to systematically *wedge those doors open* with one persuasive discovery after another over the last few short decades.

The world of animal cognition we enjoy today, which this encyclopedia showcases so well, was unimaginable not long ago. For example, this author did her PhD under Frans de Waal on the development of reconciliation – studying how capuchin monkeys learn to apologize as youngsters. Capuchins were a good model because they grow up faster and are not quite as conscious of being studied as are apes and humans. During the final defense, this author was repeatedly questioned by a committee member about the role of personality in the capuchins' peacemaking behavior. "But we don't talk about personality in monkeys!" was her startled defense, as she cast entreating glances to Frans to help her out. The questioning committee member was a human psychologist. He was incredulous that animal behaviorists dared not invoke personality or emotion in the animals we studied (if they wished to avoid professional crucifixion). Denying things like personality and emotions was very hard and always awkward. Yet that denial was still largely the tenor

of the time. Where did the invisible wall that completely blocked legitimate investigation of fascinating possibilities of animal cognition come from?

There is little question where it came from. René Descartes was wrong when he claimed that animals were stupid machines – organic automata without thoughts or feelings. But that did not stop three centuries of people from believing him. Descartes' application of logic when seeking to understand the natural world produced many cutting edge contributions to philosophy, mathematics, and science. For example, it was Descartes who introduced skepticism as an essential part of the scientific method, which includes the contemporary practice of methodological skepticism. These contributions gave him great credibility. If Descartes said animals were stupid machines, then they must be.

Descartes' simple assurance of the superiority of humanity over animals even effectively silenced countless centuries of lessons, we had learned about animal behavior before his notorious birth in 1596. These lessons extended far back to our dim past as "Man the Hunter" whose survival depended on his knowledge of prey behavior, but of the behavior of the predators that stalked him as well. These lessons are accumulated through the domestication of animals, discovery of agriculture, and establishment of farms and farm animals. They accrued through the age of grand estates – think cheetahs lounging in ancient Egyptian palaces – and more recently in animal collections on private estates and in zoological gardens, the latter in name only, because of the small, hard, empty cells we gave the animals to live in.

The point is that Descartes' simple proclamation that animals were stupid machines erected a wall that has been simultaneously invisible and omnipresent for the past three centuries. Those walls even surrounded universities, despite scholars' best efforts to study animal behavior objectively. Contemporary scholars of all forms of animal behavior have all been thoroughly basted and baked in the Cartesian animals-are-stupid-machines attitude, a reality that demands their most profound consideration.

In this author's own lifetime, a few intrepid individuals dared to scale those tall and terrible Cartesian walls. One was a boy born in 1948 in the land of tulips and windmills (Den Bosch, the Netherlands). His mother taught him that the saddest sight was a bird in a cage. This kind of thinking, along with exposure to the brilliant ethologists of his day, gave the boy his special sympathy for animals. He henceforth developed a single-minded desire to understand animals clearly and realistically on their own terms. Unbeknownst to the earnest lad who went on to study biology in Nijmegen and Groningen, the Netherlands, his single-minded desire meant spending his life slamming his shoulder against Descartes' invisible wall.

He did his PhD project at Utrecht University. As he patiently recorded aggressive behavior among macaques, he saw the glimmerings of the other side of aggression: peacemaking. To earn some money, the sprouting young man helped the psychologists in Nijmegen, the Netherlands, who worked with chimpanzees. When Frans de Waal saw the chimps, it was love at first sight.

It is hard to doubt someone you love. But Frans knew for himself what Descartes said famously aloud, "If you would be a real seeker after truth, it is necessary that at least once in your life you doubt, as far as possible, all things." Frans has done exactly that – doubt – systematically and empirically across his entire career. Frans used Descartes' own methodological skepticism against his terribly unjust invisible walls by questioning the claim that animals were stupid machines.

So Frans studied chimpanzees with fresh eyes, questioning the answers. Could all this bowing, bravado, kissing, and alliance shifting really occur without the chimps grasping at least the basics of planning, social calculations, and consequences? Did conflict *really* disperse opponents? Frans' discovery of chimpanzee politics and peacemaking was his first big shoulder shove against that invisible Cartesian wall. The wall creaked.

And he gave the rest of us a foothold. He refined the technique of providing empirical evidence for reconciliation when he designed a user-friendly, empirically elegant method. This

wedged open a sliver of a slit in that invisible Cartesian wall. It has since widened considerably with the passage of scores of investigators who used Frans' PCMC method to reveal peacemaking in other species, including my own demonstration of reconciliation in bottlenose dolphins.

The author met Frans when he came to study the bonobos at the San Diego Zoo, where she worked. He was just the "guy from Europe." He was fun. He did not fanfare the guts it took to put "chimpanzee" and "politics" together in the title of a book. Nor did he complain that the tenor of the times insisted that his use of the word reconciliation (to describe peacemaking gestures after two chimps fought) was inevitably attended by the caveat "heuristic label" because, after all, animals were not exactly robotic automatons, but almost.

Frans kept heaving his shoulder against that invisible Cartesian wall. He led contemporary students of animal behavior and cognition in another direction with cross-fostering experiments. These not only demonstrated that peacemaking has a strong learning component. They encouraged animal behaviorists to conduct observation-based experiments. No Skinner box is needed.

Frans heaved his mighty shoulder against that invisible Cartesian wall again when he demonstrated how mere observation could be used to reasonably correlate behaviors that were staggered in time: I groom you this morning. You share food with me this afternoon. Who thought animals were paying attention like that? The chimps taught Frans that social interaction was a transaction. No exchange was without impact. This time, a couple of big boulders tumbled out of those invisible Cartesian walls.

Frans kept heaving. In turning Cartesian skepticism around, Frans invoked possibilities of animal behavior that few others dared consider: planned social strategies that included third party interventions, cooperation, reciprocity, and peacemaking, but also justice, altruism, fairness, consolation, food sharing, and generosity. With such a tool chest, social interaction becomes a series of transactions with consequences. Animals had to remember and to think ahead.

Citing parsimony, Frans argued for evolutionary continuity with empirical evidence that empathic and cooperative tendencies are continuous across species. He argued that empathy is one of the emotional roots of morality. It had evolutionary roots far deeper than our own. Equitable attitudes are universal mammalian characteristics. Though the idea remains unwelcome in many quarters, one conclusion had to be that nonhuman great apes and humans are simply different types of apes. Nonetheless, humans are more systematically brutal than chimps and more empathic than bonobos. "Our societies are never completely peaceful, never completely competitive, never ruled by sheer selfishness, and never perfectly moral," Frans pointed out when calling us the bipolar ape!

No one familiar with Frans' work has to be persuaded that he has unique vision. His penetrating views of the cognitive basis of animal behavior have given us a rich vocabulary for seeing animal behavior the way digital glasses give a 3D image in profound depth, color, and realism.

Little wonder that Frans is C. H. Candler Professor of Psychology at Emory University and the Director of the Living Links Center at the Yerkes National Primate Research Center and has been a University of Utrecht Distinguished Professor since 2014. In 2007, *Time* magazine included him in the "TIME 100: The People Who Shape Our World," a list of the 100 most influential people. He was elected to the Dutch Academy of Sciences in 1993 and to the National Academy of Sciences in 2004. His books have been translated into over 20 different languages, and he probably wrote one in the time it took me to write this biography. He is married and lives close to Atlanta, where he and his wife Catherine throw generous parties so their graduate students can enjoy a moment of misty equality.

Frans told this author that he thought his greatest contribution to animal behavior and cognition studies was probably his discoveries of conflict resolution and empathy. To this author, Frans' greatest contribution was role modeling *how* to tease evidence out of benign observation by designing experiments that did not traumatize anybody involved – except Lance the capuchin,

whose tantrum-like recognition of the unfairness of getting a cucumber reward when his compatriot got a grape went viral on the Internet!

Frans has worked single mindedly to put animals in a whole new light and reverse the appalling Cartesian sanction to brutalize them with impunity. Frans is not the only animal behaviorist to assault those invisible Cartesian walls with an academic battering ram, as this encyclopedia amply portrays. It was just that Frans' ram grew huge with time, and he hit those walls harder and more often than most. The last time this author saw Frans, she thanked him for casting such a bright light that so many of us could bask in his reflected glory. Frans' greatest contribution to animal cognition was to storm those Cartesian walls open. Because of his work, contemporary students of animal behavior and cognition are free today to actually explore these fascinating topics without the constraints of the past.

Frans, how does it feel to be your very own personal paradigm shift?

## Fraternal Birth Order Effect

Scott W. Semenyina  
University of Lethbridge, Lethbridge, AB,  
Canada

## Synonyms

[Birth order](#); [Male androphilia](#); [Male sexual orientation](#); [Maternal immune hypothesis](#); [Older brother effect](#)

## Definition

The *Fraternal Birth Order Effect* (FBOE) is the well-established finding that each biological older brother a male has increases the likelihood that he will be same-sex attracted.

## Introduction

In humans, having a greater than average number of biological older brothers is reliably associated with an increased probability of male homosexuality. The Fraternal Birth Order Effect (FBOE) is among the most consistently established correlates of male sexual orientation (Blanchard 2017), being linked to male homosexuality in diverse populations throughout the world. These include Western samples drawn from the United States, Canada, the United Kingdom, Italy, and the Netherlands, as well as non-Western cultures such as Brazil, Turkey, and Samoa (reviewed in Blanchard 2017; Blanchard and VanderLaan 2015). Some studies have reported that homosexual males also have an elevated number of older sisters relative to heterosexual comparison groups. It is important to note that homosexual males tend to have larger families in general than heterosexual males (Bailey et al. 2016). Additionally, no plausible mechanisms exist for an older sister effect, and only older brothers predict male homosexuality after controlling for overall number of siblings. As such, this “older sister effect” is simply due to the fact that having more older brothers is correlated with having more older sisters as well (Blanchard 2014, 2017; VanderLaan and Blanchard 2015). Similarly, many studies that found no FBOE in their original analyses *do* reveal an effect of older brothers when properly controlling for family size (Blanchard 2017). Some studies have also looked for a possible birth order effect in the origins of female homosexuality, but female sexual orientation appears to be unaffected by sibling characteristics (see Blanchard 2004).

The FBOE for male sexual orientation has been established in modern populations and in decades old archival samples, among both homosexual males who identify as men and homosexual males who identify as transgender women (or culturally specific third-gender categories), and even among individuals with sexual attraction to prepubescent and pubescent males. Although the FBOE is related to sexual attraction specifically, a recent meta-analysis has shown that it may be implicated in gender expression as well.

The FBOE appears to be stronger in homosexual males who are transgender, as compared to the strength of the effect among homosexual men (Blanchard 2017). The reasons for this difference are currently unclear. It is possible that the FBOE feminizes both sexual preference (i.e., attraction to males) along with traits associated with a feminine gender presentation, or that the FBOE is in some way more “feminizing” than other mechanisms leading to male homosexuality, such as genetics or hormone exposure in utero. Despite the varied populations examined, numerous replications of the FBOE confirm the same general pattern – each older brother that a natal male has increases the probability of homosexual attraction.

Specifically, each biological older brother that a male has increases the odds of same-sex attraction by approximately 33% (odds ratio = 1.33) over the baseline rate of male homosexuality (~2–4%) (Cantor et al. 2002; Blanchard 2014; VanderLaan and Vasey 2011). Given this increase, and assuming a linear effect, a male with 10 older brothers would stand roughly a 50% chance of being homosexual (i.e., odds ratio \* number of brothers \* base rate of homosexuality =  $1.33 * 10 * 0.04 = 0.532$ , or 53.2% chance of being homosexual). It is estimated that overall, 14–29% of homosexual males owe their sexual orientation to the FBOE (Blanchard and Bogaert 2004; Cantor et al. 2002), meaning that at least one in seven homosexual males owes their sexual orientation to the FBOE.

Work on the FBOE was pioneered in the early 1990s, spurring numerous studies into both its existence and possible mechanisms by the original investigator (Canadian psychologist, Dr. Ray Blanchard), as well as others. Independent replications of the FBOE are numerous, and persist even in meta-analyses that specifically exclude scientific reports published by Blanchard and his usual collaborators (see VanderLaan and Blanchard 2015). Nonbiological siblings have no impact on male sexual orientation, nor does time spent with these siblings, meaning that the FBOE is specific to *biological* older brothers (Bogaert 2006). Indeed, the FBOE persists whether individuals are raised together with, or separately

from, their biological older brothers (Bogaert 2006). Such evidence is consistent with the suggestion that male homosexuality is biological in origin, the result of pre-natal, rather than post-natal influences (Bailey et al. 2016; Bogaert 2006). The causal mechanism of the FBOE is pre-natal in origin, with the most likely explanation involving the influence of the maternal immune system impacting the neural development of her male fetus.

The most prominent explanation for the FBOE is the Maternal Immune Hypothesis (MIH). While there is currently no direct laboratory evidence, ample circumstantial evidence converges on the MIH being the most likely causal mechanism underpinning the FBOE (Blanchard 2004; Bogaert and Skorska 2011). The MIH proposes that each male fetus a woman carries heightens the probability that she is exposed to male-specific antigens produced by the Y-chromosome, which are foreign to her immune system. Increased exposure to male specific (Y-linked) antigens provokes a progressively stronger immunological response, which in turn can cross the placental barrier, impacting the brain development of a male fetus. As such, every male fetus a mother carries increases the likelihood of exposure to Y-linked antigens, and in turn makes it more likely that a subsequent male fetus will be exposed to maternal antibodies. The heightened immunological response of a mother to Y-linked antigens is hypothesized to disrupt the sexual differentiation of a male's brain, including key regions linked to sexual orientation such as the hypothalamus (Blanchard 2004; Bogaert and Skorska 2011; Blanchard 2017). At least four candidate antibodies have been identified as specific mechanisms of the MIH (PCDH11Y, NLGN4Y, TBL1Y, SMCY) (Bogaert and Skorska 2011), but confirmation that these specific proteins are directly responsible for the FBOE awaits further histological confirmation in the laboratory.

## Conclusion

In summary, a greater than average number of biological older brothers is consistently associated

with male homosexuality across numerous diverse populations. Reliable effects emerge across studies, especially when controlling for family size (Blanchard 2017). While the existence of the fraternal birth order effect (FBOE) is firmly established, the exact causal mechanism requires further investigation. The FBOE is most likely caused by maternal antibodies that target male-specific proteins, disrupting the typical neural development of the male fetus. Future work on the FBOE could include both laboratory studies of candidate proteins (Y-linked antigens) that are targeted by maternal immune factors, as well as longitudinal studies examining pre-natal factors in pregnant mothers and the post-natal outcomes of their male children's sexual orientation.

## Free Operant Response

Sydney Trask

The University of Vermont, Burlington, VT, USA

## Synonyms

[Instrumental behavior](#)

## Introduction

Typically studied in the laboratory using an operant chamber (or “Skinner box”), operant, or instrumental, behavior can be generally described as a freely emitted behavior that has an effect on the environment. For example, a rat might learn to press a lever in order to produce a food outcome or produce an intravenous injection of a drug such as

cocaine (see “Self-Administration”). Thus, operant conditioning is a relatively simple and straightforward method used to study variables that influence voluntary behavior. Free operant behavior refers to an operant behavior that has a schedule of reinforcement (see “Operant Conditioning”; Ferster and Skinner 1957 for an extensive review on reinforcement schedules) that is in effect for the duration of the time the animal is in the operant chamber with no constraint on the number of responses the animal can emit while in the chamber. Thus, responding and reinforcement schedules in a free operant design are not limited to discrete periods or trials. Free operant behavior can be contrasted with discrete trial operant behavior, in which only one response can be made per trial (e.g., performance on a maze task). Further, discriminated operant procedures, in which the schedule of reinforcement is in effect only in the presence of a discrete discriminative stimulus, or  $S^D$ , such as a tone or the illumination of a panel light can be differentiated from standard free operant procedures in that the reinforcement schedule is not in effect when the  $S^D$  is not present, whereas the reinforcement schedule is not constrained to a discrete period in free operant procedures (Skinner 1938).

## Association Formation During Free Operant Conditioning: What Learning Underlies Responding?

Traditionally, the role of the reinforcer (an outcome that increases the likelihood of future responses) or a punisher (an outcome that decreases the likelihood of future responses; see “Operant Conditioning”) in free operant behavior was thought only to strengthen or weaken (respectively) the response, making it more (or less) likely to occur in the presence of the stimuli available when the response was reinforced (or punished). Thus, the counterintuitive prediction made by this view is that the consequence does not actually get encoded into the associative structure that promotes instrumental responding. In other words, responses were thought to be performed mindlessly without explicit knowledge or in pursuit of the outcome. However, given that responding is lawfully tied to

outcome delivery, the associative structure should thus depend in part on knowledge of the outcome. To test for this, the so-called “reinforcer devaluation method” is used. In a standard version of this paradigm, an animal is taught to perform a behavior (e.g., a lever press) for a food outcome. Once this behavior is established, the animal has the reinforcer “devalued” in some way, typically, through pairing its presentation with a lithium chloride induced illness (which conditions a taste aversion to the outcome) or through a satiation procedure in which the animal is allowed to consume as much of the outcome as he wants. Then, in a crucial test, the animal is placed back in the chamber and responding is tested without any outcome presentations. If the animal has knowledge of the outcome produced by the response (i.e., the animal has knowledge of a response–outcome, or R – O, association), then behavior should be suppressed for an outcome that has been devalued. This demonstrates that responding is goal-directed in nature. Overall, research suggests that responding is typically goal-directed early on in training (i.e., responding is suppressed following devaluation) but that following extensive training in which the response is paired with the outcome, the reinforcer devaluation effect on responding is not observed and behavior is described as habitual. This suggests that behavior is initially dependent on an R – O association for expression, but gradually comes to rely on an S – R association (Dickinson 1985).

### **Contextual Control of Free Operant Responding: Associations Between the Context and the Response**

Although, as previously discussed, in standard, nondiscriminated free operant procedures there is no discrete stimulus or  $S^D$  that signals that responses will be reinforced, free operant responding depends crucially on the acquisition context for expression. Thus, a change to a new context (i.e., a new operant chamber with different tactile, visual, and olfactory cues) consistently results in a decrement in operant performance. This suggests that the context is an important

part of the associative structure that underlies instrumental learning. The context can come to signal the response–outcome association in a hierarchical Context – (R – O) relationship in which the context signals that a certain response will produce an outcome. The context can also come to elicit the response directly in a Context – R association. In the case of free operant behavior, the context is likely the stimulus (or S) that supports habitual S – R performance (see Trask et al. 2017, for a review).

### **Influence of Stimuli on Free Operant Responding: Pavlovian-Instrumental Transfer**

Free operant responding that does not involve learning to perform a response in the presence of a discrete stimulus or  $S^D$  can still be influenced by stimuli in a paradigm known as Pavlovian-Instrumental Transfer, or PIT, in which a stimulus associated with a reinforcer can invigorate instrumental responding. A typical PIT experiment involves training of an instrumental response to produce an outcome and pairing of a conditioned stimulus with the same outcome in separate phases. Following this training, the response is available (but not reinforced) and tested with the conditioned stimulus. The typical result is that, despite never having been trained as an  $S^D$ , the conditioned stimulus will elevate responding. The opposite is also true; a conditioned stimulus paired with an aversive unconditioned stimulus (e.g., a shock) will result in a suppression of the response. In this way, Pavlovian stimuli can guide or motivate instrumental responding despite a lack of explicit training (Bouton 2016).

### **Operant Extinction and Relapse**

Previously reinforced free operant behavior can become inhibited or suppressed when the response no longer produces a reinforcer in a process known as extinction (note that, although both procedures cause a reduction in responding, extinction differs from punishment in that a punisher is a consequence of a response; extinction is programmed such that responses explicitly have no consequences). While, behaviorally, this

initially looks as though the original behavior is erased, several “relapse” phenomena suggest that the original behavior remains intact and responding can return under certain circumstances (Todd et al. 2014). Briefly, these relapse phenomena are renewal (a return of extinguished responding due to a removal from the physical context where extinction occurred), spontaneous recovery (i.e., a return of extinguished responding due to the passage of time), reinstatement (i.e., a return of extinguished responding due to exposure to the reinforcing outcome), and resurgence (i.e., a return of extinguished responding due to the removal of alternative reinforcement contingent upon a second response). It has been hypothesized that operant behavior results in formation of an inhibitory stimulus-response association between the context in which extinction takes place and the response. Thus, the animal learns not to perform a response in the extinction context (Rescorla 1997; Trask et al. 2017).

## Conclusion

Free operant behavior (and operant conditioning more generally) provides a useful method to study the variables that influence voluntary behavior. While this method is theoretically interesting and a fruitful area of investigation in its own right, it also provides a useful laboratory model for understanding maladaptive voluntary behavior, such as over-eating, smoking, and drug-taking. Further, this training can contribute to our understanding of the mechanisms that produce relapse of these behaviors following procedures that reduce responding, like extinction and punishment.

Forced desynchrony; Nonentrained

## Definition

An endogenous circadian rhythm or behavior that is not synchronized to any external cue.

## Introduction

In 1938, Dr. Nathaniel Kleitman and his graduate student, Bruce Richardson, spent 32 days deep within the Mammoth Cave in Kentucky. Their goal was to understand what happens to daily circadian cycles (derived from the Latin terms *circa*: approximately, *dies*: day) in the absence of daily environmental cues (i.e., without the normal daily changes in light and temperature caused by the Earth's rotation). The cave was ideal for this experiment as it was always dark, it had a constant temperature, and it was isolated from outside noise and human interaction. To separate the normal sleep and wakefulness cycle from any internal circadian rhythms, the investigators chose to live on a 28-h day-length (i.e., one sleep bout every 28 h), and they recorded their body temperatures at regular intervals. After over a month of living in the cave, they found that body temperatures can

keep a near 24-h rhythm, suggesting that humans have an endogenous time-keeping system which is self-sustained in the absence of environmental time cues, and even persisted when the sleep and wakefulness cycle had a different period (28 h). After recreating this cave-like environment with different day-lengths (e.g., 20-h or 28-h “days”) in controlled laboratory settings (dim-lighting, constant temperature, equally distributing behaviors across the entire circadian cycle), we now know that this circadian timing system has an endogenous period that is close to but not exactly 24 h, and that this period is slightly different between people, averaging around 24.2 h (Czeisler et al. 1999). In the absence of time-cues, the circadian rhythm will cycle with this endogenous period; in these conditions, it is known as a “free-running” circadian rhythm. This type of protocol – free of environmental time-cues and of differing day-lengths – has been important because it has helped to uncover the endogenous nature of the body clock, the quantification of the endogenous circadian period, and has allowed investigators to assess the circadian rhythms of many physiological and behavioral variables, and their interactions independent of outside influence. Further, these discoveries have allowed us to understand why certain populations, such as some blind individuals, have trouble maintaining a 24-h schedule as they lack the pathway to synchronize to the 24-h day and thus exhibit free-running circadian rhythms.

## The Circadian System, Entrainment, and Free-Running Cycles

In mammals, the circadian timing system is controlled by a central pacemaker, or master clock, located in the suprachiasmatic nucleus (SCN) of the anterior hypothalamus. The SCN is composed of approximately 20,000 neurons; among these, many are individual autonomous oscillators. When studied in a dish – the “Mammoth Cave” for cells where external timing cues can be eliminated – SCN neurons exhibit free-running rhythms of electrical activity and gene expression

with periods close to 24 h (Welsh et al. 1995). SCN neurons use both neuronal and humoral outputs to communicate timing information to peripheral clocks located throughout the body (e.g., kidneys, gut, pancreas, etc.), synchronizing these peripheral clocks with the master clock to organize biological functions for anticipation of changes in the environment (e.g., promote wakefulness, feeding, and motor activity for the daytime, and promoting sleep or resting behavior for the nighttime) (Schibler and Sassone-Corsi 2002). The duration of the rhythm produced by the SCN, however, most often does not exactly match the Earth's 24-h rhythm and thus must be synchronized or entrained on a daily basis to match physiology and behaviors with the Earth's 24-h light-dark cycle. Circadian entrainment is the process of achieving a stable phase relationship between the timing of a circadian marker (e.g., peak cortisol secretion, melatonin onset, core body temperature minimum, etc.) and a periodic environmental time cue (e.g., lights-on, lights-off). When entrainment does not occur, rhythms will instead free-run at their own endogenous period (Fig. 1).

Circadian clocks are ubiquitous on Earth and they are phylogenetically diverse, having been studied in all branches of life. The mechanisms that encode circadian rhythms are diverse as well, and differ between bacteria, fungi, plants, and animals (Edgar et al. 2012). Animals may be broadly categorized as being active during the day (diurnal), night (nocturnal), or twilight (crepuscular). Though exceptions exist, diurnal animals tend to have free-running periods greater than 24 h and nocturnal animals tend to have free-running periods less than 24 h (Aschoff 1981). The average circadian period in humans is ~9 min longer than the Earth's 24-h light-dark cycle (Czeisler et al. 1999), while a typical laboratory mouse may have a free-running period closer to 23.5 h. Thus, these circadian rhythms must be continually entrained to 24 h by exogenous stimuli. Although nonphotic cues can synchronize circadian rhythms, in most animals, including humans, light is the primary zeitgeber ("time-giver") for the circadian system (Czeisler and Wright 1999). In mammals, light is detected by

**Free-Running Cycle, Fig. 1** Simulated wheel running record of a nocturnal rodent that is entrained to the 24-h day and then placed into a dim-lighting environment, whereby entrainment no longer occurs and the activity rhythm free-runs at the rodent's endogenous circadian period (<24 h in this example). *White bars* represent room lighting and the *gray bars* represent dim-lighting. The *black ticks* indicate wheel-running activity

photoreceptors in the retina. A specific set of retinal ganglion cells, which contain melanopsin and are intrinsically photosensitive, transmit this photic information through direct projections to the SCN via the retinohypothalamic tract (Hattar et al. 2002). The response of the circadian system to light depends on the timing of exposure. Light exposure in the early biological night causes the circadian clock to shift to a later time (phase delay); light exposure in the early biological morning causes the circadian clock to shift to an earlier time (phase advance) (Khalsa et al. 2003). Thus, to remain entrained to the Earth's 24-h environmental cycle, individuals or species with a circadian period that is longer than 24 h require a daily phase advance and those with a circadian period that is shorter than 24 h require a daily phase delay.

The eyes are necessary for entrainment of free-running circadian rhythms in mammals, but this is not the case for other branches of life. Circadian rhythms of reptiles and birds can be entrained by light that penetrates the skull and activates deep-brain photoreceptors. For single cell cyanobacteria, light entrains their circadian clocks by changing the ratio of ATP to ADP. This last example highlights the close connection between clocks and metabolism, which is a hallmark across phylogeny (Asher and Schibler 2011).

Maintaining an appropriate relationship between the phase of the internal clock and the timing of the external environment and behaviors (e.g., the sleep/wake) is vital for healthy cognitive and physiological functioning. Individuals with a free-running rhythm, common in blind individuals lacking an entraining photic pathway, typically have difficulty as their non-24-h clocks drift in and out of phase with work, social, and sleep schedules dictated by the Earth's 24-h day (Sack et al. 2007). In this regard, one particular non-photic zeitgeber deserves mention: the hormone melatonin is synthesized and released during the night; it is also a chronopharmacologic agent that advances the clock in the evening and delays the clock in the morning (opposite to the effects of light). For free-running blind people, evening or morning melatonin (depending on whether the person's free-running rhythm is longer or shorter than 24 h) can therefore entrain them to the 24-h day. The consequence of a free-running period that is not exactly 24 h is that the daily behaviors, such as sleeping and eating, must shift each day relative to the external time (e.g., GMT) or else result in a state of almost permanent "jet lag," when the daily behaviors occur at suboptimal circadian times. This condition is called circadian misalignment and is most noticeable as the acute nausea and sleepiness that often accompanies jet travel across many time zones or when changing work schedules, such as starting night shift work. Indeed, poor health has also been attributed to the chronic occurrence of circadian misalignment, which testifies to the importance of the internal circadian system in optimizing our physiology and behaviors.

## Conclusion

Most animals have an endogenous circadian clock that is not exactly 24 h, and thus require a daily entraining stimulus (e.g., light) to remain synchronized to the Earth's 24-h rotation. When this entrainment is interrupted either by scientific manipulation or disruption of the entrainment pathway, the organism's endogenous circadian rhythm will become a free-running rhythm and express its intrinsic circadian period.

### Definition

Relative distribution of the specific observable traits, or “phenotypes,” in the individuals of a population like physical characteristics (i.e., height, weight, skin color, etc.) or the behavioral features (i.e., attitude, aggression, nervousness, altruism, etc.), which may vary individual to individual.

### Introduction

To study the frequency distribution of a specific observable trait or a “phenotype” in a population is an important aspect of quantitative genetics (Halliburton and Halliburton 2004). The phenotype meant an expressed characteristic of an organism, like physical characteristics (i.e., height, weight, skin color, etc.), or a particular behavioral feature (i.e., attitude, aggression,

## Relative Phenotype Frequency

The number of individuals in a population bears a specific observable trait or phenotype is called as “relative phenotype frequency.” The relative phenotype frequency for a phenotype can be calculated by counting the number of times a particular phenotype appears in a population and dividing it by the total number of individuals in the population. The relative frequency of the observed phenotypes in a population can be assembled together to show the frequency distribution of the set of phenotypes (“[The Variety of Genes in the Gene Pool Can Be Quantified within a Population | Learn Science at Scitable](#)”).

## Graphical Representation of the Phenotypic Frequency Distribution

Frequency distribution of a phenotype is studied in a population and presented in bar graphs or histograms. For discrete or discontinuous traits, a qualitative statistical test as Chi-square test is applied and the frequency distribution is presented in line or bar graphs, or pie diagrams. A continuous trait can be measured on a set scale and charted in histograms. As continuous trait may bear any value in a defined measuring system, all statistical tests using central tendencies (i.e., mean, median, mode) can be applied to it and show a typical bell-shaped standard curve if measurement values are presented in a histogram (Minter 2003). Figure 1 shows the example of the frequency distribution histogram for a continuous trait as height in an assumed population. At the extreme values

**Frequency Distribution of Phenotypes, Fig. 1** Frequency distribution for the height of individuals in an assumed population

towards both ends, there are minimum numbers of individuals, and the higher numbers of individuals are at the mid-values progressively, mimicking the frequency distribution of trait in a natural population which will give a typical bell-shaped standard curve in the histogram.

allele would not be convertible into a phenotype if the organism is not carrying all alternative forms. Genotype or allelic frequency distribution for a phenotype is a quantifiable property and can be estimated using Hardy-Weinberg principle if the dominance or recessive traits for the alleles are known.

## Phenotype Versus Genotype Versus Allele

Phenotype depends on the genetic makeup or “genotype” of an organism at a particular gene locus. Genotype is the particular allelic combination at a gene locus which will give rise to a trait. Alleles are the alternative forms a gene present at a specific locus.

Phenotype frequency distribution can be also derived from the genotype or allelic frequency or vice versa for a particular trait in a population. But a genotype is not always equal to a phenotype, as some characteristics only express in the organism depending upon that allelic combination for the trait is either dominant or recessive. A recessive

## Hardy-Weinberg Equilibrium Principle

Hardy-Weinberg equilibrium principle is used to predict the frequencies of alleles and genotypes in a population. It states that genotypic or allelic frequencies in a population remains constant or maintain a state of equilibrium in the absence of any disturbing factors, i.e., the sum of all possible outcomes must be equal to one. For example, if “p” and “q” are the two alleles for a particular gene, then  $p + q = 1$ , or if there are three alleles (p, q, and r) for a particular locus of a gene, then  $p + q + r = 1$  (Halliburton and Halliburton 2004).

The disturbing factors to the Hardy-Weinberg equilibrium can be many including mutations,

natural selection, nonrandom mating, genetic drift, and gene flow. The mutations disturb the equilibrium of allele frequencies by introducing new alleles into a population. Similarly, natural selection and nonrandom mating may disturb the Hardy-Weinberg equilibrium by changing gene frequencies due to bias for a favorable trait (“[Hardy-Weinberg equilibrium | Learn Science at Scitable](#)”).

Contrary to the assumption, the desired state of equilibrium in – Hardy-Weinberg principle, which is used as a model for studying real populations – can never be achieved in a real population but only can be approximated in the laboratories in ideal conditions. There are certain criteria which need to be fulfilled so a population ideally can achieve Hardy-Weinberg equilibrium (Box 1).

#### Box 1 Criteria to be fulfilled for Hardy-Weinberg equilibrium

- Population is large
- Mating is random
- Allele frequencies are equal in the sexes
- There is no migration, mutation, or selection

### Genotype, Allelic, or Phenotype Frequency Estimation Using Hardy-Weinberg Equilibrium Principle

How to calculate genotype or allelic frequency if relative phenotype frequency for an observable trait is known or vice versa can be understood from the following sample problem.

#### Sample Problem

1. Let us assume a mice population where individual bears either of two color phenotypes black or white. Black mice are 36% and remaining is white. Now calculate the allelic and genotype frequencies using the Hardy-

Weinberg equation (assuming that population is at equilibrium).

- (a) Let us consider the gene for color trait has two alleles A (dominant) and a (recessive)
- (b) The frequency of allele A is represented by p
- (c) The frequency of allele a is represented by q
- (d) The frequency of genotype AA =  $p^2$
- (e) The frequency of genotype Aa = pq
- (f) The frequency of genotype aa =  $q^2 = 36\% = 0.36$  (so  $q = 0.6$ )

### Alleles and Allelic Frequency

|                                   |   |
|-----------------------------------|---|
| Frequency of dominant allele (A)  | p |
| Frequency of recessive allele (a) | q |

Hardy-Weinberg equation for allelic frequency:  
 $p + q = 1$ .

### Genotype Frequency

| Observed Trait       | Genotype | Frequency | Phenotype |
|----------------------|----------|-----------|-----------|
| Dominant homozygous  | AA       | $p^2$     | White     |
| Heterozygous         | Aa       | pq        | White     |
| Recessive homozygous | aa       | $q^2$     | Black     |

Hardy-Weinberg equation for genotypic frequency:  $p^2 + 2pq + q^2 = 1$ .

### Steps in Solving Problems Using Hardy-Weinberg Equation

1. Assign the frequency of dominant and recessive alleles (dominant as p and recessive as q).
2. Calculate q by taking the square root of the number of homozygous recessive individuals.
3. Calculate p ( $p + q = 1$ , so  $p = 1 - q$ ).
4. Using values of p & q, calculate the genotype frequencies ( $p^2$  – frequency of dominant homozygous genotype,  $2pq$  – frequency of heterozygous genotype,  $q^2$  – frequency of recessive homozygous genotype).

**Step 1**

Let us assume that dominant allele “A” which bears frequency “p” stands for white color, and recessive allele “a” which bears frequency “q” stands for black color.

**Step 2**

The key to solving frequency distribution problems lie in the number of homozygous recessive individuals because they can be easily identified.

$$q^2 = 36\%, 0.36, \text{ so } q = 0.6$$

**Step 3**

$$p + q = 1, \text{ so } p = 1 - q$$

$$\text{So } p = 1 - 0.6 = 0.4$$

**Step 4**

$$p = 0.4, \text{ so } p^2 = 0.16 \text{ or } 16\%$$

$$2pq \text{ (heterozygous)} = 2 \times 0.4 \times 0.6 \\ = 0.48 \text{ or } 48\%$$

Verifying the values with the original equation for genotype frequency estimation,

$$p^2 + 2pq + q^2 = 1 \text{ or } 0.16 + 0.48 + 0.36 = 1$$

Using the Hardy-Weinberg equation, if genotype or allelic values and dominant/recessive traits are known, phenotype frequency distribution can be also derived.

**Frequency-Dependent Selection**

Kavita Krishnamoorti

Genetics Laboratory, Department of Zoology,  
Institute of Science, Banaras Hindu University,  
Varanasi, India

**Synonyms**

Antipostatic selection; Minority advantage;  
Rare-type advantage

**Definition**

Frequency-dependent selection occurs when the fitness of genotypes vary as a function of the genotypic composition of the population.

**Introduction**

Frequency-dependent selection is a type of natural selection where the fitness of a given genotype depends on its frequency in the population.

Frequency-dependent selection is operated via **negative frequency-dependent selection (rare-type advantage)**, where the fitness of a genotype/phenotype increases when its frequency in the population is rare, and **positive frequency-dependent selection**, where the fitness of a genotype/phenotype increases when its frequency in the population is abundant.

In the development of the concept of frequency-dependent selection, interest was clearly focused on negative frequency-dependent selection because of its theoretical importance. Suppose that there is an allele  $A_1$  which is dominant over  $A_2$  and  $A_1A_1$  and  $A_1A_2$  have the same fitness, which is different from that of  $A_2A_2$ . If the fitness of  $A_1A_1$  and  $A_1A_2$  is higher than that of  $A_2A_2$  when  $A_1$  is rare, but becomes lower when  $A_1$  is frequent, so that, a stable polymorphism can exist (Charlesworth and Charlesworth 2010). Thus, this type of selection mechanism is essential for maintaining the genetic variability in population.

### Examples of Frequency-Dependent Selection

Many examples are available which confer that negative frequency-dependent selection occurs more commonly. One example is **apostatic selection**, in which there is selection by predators that learn while they hunt; this favors rare forms of prey (Clarke 1969). Vertebrate predators, such as birds, tend to form search images of their prey. For example, if a snail with a particular shell color is encountered, and is found to be good to eat, the bird will look out for more of the same. Rare color variants that differ from the majority of the population will tend to be ignored and experience lower predation rates. This will cause them to rise in its frequency, but the birds will then start to encounter them more frequently. The selective advantage will then decrease, possibly resulting in a stable equilibrium with both forms present. Similar studies have shown that the strength of the observed selection is affected by prey density, palatability, coloration, and conspicuousness. When the prey density is very high, sometimes

selection becomes “**antiapostatic**”: predators preferentially remove rare prey.

Another very important example is a system in which frequency-dependent selection causes the maintenance of polymorphism in self-incompatibility in hermaphroditic species of plants (Wright 1939; Vekemans and Slatkin 1994; Schierup et al. 1998). Genetic studies of plant species with an inability to self-fertilize have shown that these are often controlled by one or a small number of “ $S$  loci,” which are among the most highly polymorphic genes known in terms of numbers of alleles (Richman et al. 1996; Sato et al. 2002). The simplest such system involves a single gametophytic self-incompatibility locus, found in plants. Pollen grains carrying an allele  $S_i$  at the  $S$  locus cannot fertilize ovules of plants that also carry  $S_i$ , and these pollen grains tubes usually fail to grow down the stigma to the ovary. This means that all plants in the population are heterozygous for two different  $S$  alleles, and that there must be at least three of these for the plant to be able to cross-fertilize each other and allow the population to survive. Usually, at least a dozen or more  $S$  alleles are found in a population. A mutation that creates new  $S$  alleles will have a selective advantage, since pollen carrying a new variant can fertilize any plant in the population, whereas pollen carrying an established allele cannot fertilize the fraction of the population that carries that allele. This selective advantage will decline as the new allele increases in frequency; if the alleles have no other effects on fitness, equilibrium will be achieved when all possible heterozygotes have equal frequencies.

In *Drosophila*, the phenomenon of rare male mating (minority male mating) is an example of negative frequency-dependent selection (Singh and Sisodia 2000). It occurs when two types of males are present in unequal proportions and the females preferred that type of male whose frequency is relatively low.

A recent example of negative frequency-dependent selection in *Drosophila melanogaster* describes the maintenance of behavior polymorphism which is directly linked to naturally occurring functional alleles of the foraging (*for*) gene (Fitzpatrick et al. 2007). “Rover” (*for<sup>R</sup>*) larvae move more than “sitter” (*for<sup>S</sup>*) larvae when

foraging within a food patch, and they are also more likely to explore new food patches than are sitters. However, when they are raised in low-nutrient conditions, both of the naturally occurring alleles of foraging gene (*for<sup>R</sup>* and *for<sup>S</sup>*) have their highest fitness when rare. This effect disappears at higher resources level demonstrating the role of larval competition.

Frequency-dependent selection also arises from the relation between hosts and parasites (Haldane 1949). Possibly, many amino acid polymorphisms in the major histocompatibility complex (MHC) loci of vertebrate are maintained by frequency-dependent selection.

### Evolutionary Significance of Frequency-Dependent Selection

Balanced polymorphism is essential for maintaining the genetic variability in the natural population. This can be achieved by either heterozygote advantage or frequency-dependent selection. With constant fitness, selection acting at a single locus always maximizes the mean fitness of a randomly mating population, even though homozygotes with lower fitness are present when there is heterozygote advantage. On the other hand, when fitnesses are not constant, even if there is no heterozygote advantage, genetic variability can be maintained by other forms of balancing selection, i.e., frequency-dependent selection.

## Friendships in Animals

Jorg J. M. Massen  
 Department of Cognitive Biology, University of Vienna, Vienna, Austria  
 Austrian Research Center for Primatology, Landskron, Austria  
 Animal Behaviour and Cognition, Utrecht University, Utrecht, The Netherlands

### Synonyms

[Animal social relations](#); [Relationship quality](#)

### Introduction

Friendship in animals has long been considered an anthropomorphism, and the use of the term was

consequently a taboo. Joan Silk, while advocating the use of term, even referred to it as the “F”-word in primatology (Silk 2002). The debate about animal friendship originates, at least partly, by the lack of a proper definition. The Oxford dictionary of English defines friendship as *a relationship between friends* and more broadly as *the emotions or conduct of friends*. Whereas the former provides little help as to compare the social relationships of humans and other animals, the latter is rather subjective, be it while comparing the emotions involved in friendships of humans and other animals, or even when comparing the emotions involved in friendships of different people. Rather than discussing semantics, however, it may be useful to first have a look what friends, be it human or non-human, are actually doing.

From a more behavioral point of view, Robert Hinde (1976) defined a relationship as a series of interactions in time, and based on the nature of these interactions, in their specific context, these relationships can be defined as good or bad. Good relationships are thus defined as a series of positive interactions, and the measures that are often used to quantify such good relationships are (tolerance for) close proximity and social grooming or other forms of gentle body contact (e.g., embracing and preening) (Massen et al. 2010). As these objective measures are comparable for humans and other animals, first primatologists, and later also researchers that work on different species, have started to adopt the term friendship for such good relationships or close social bonds.

In an attempt to reconcile “costly” investments such as grooming with the theory of evolution, Hans Kummer (1978) recognized that such differential relationships do not emerge randomly, but that specific relationships have specific value. In particular, the value of a relationship may be the support or protection of the individual with whom one has such a good relationship. Later, this value of a relationship has been integrated in a more detailed and overarching description of relationship *quality* that also includes the security or consistency of a relationship, and the compatibility of a relationship (Cords and Aureli 2000). Nevertheless, this value of relationships has incited a long-

lasting debate among biologists, as well as between biologists and psychologists about the comparability of human friendships and those of other animals. Because, such short-term “business partnerships” (Barrett and Henzi 2002) are *clearly* different from the unconditional friendships of humans. In fact, Hinde’s definition of a relationship as a series of interactions *in time*, makes it inevitably dynamic and subject to short-term changes. Consequently, it is indeed important to distinguish short-term relationships that only cater current needs from long-term stable social relationships.

Many relationships of animals, including those of humans, are short-term, and interest and investment in particular relationships may follow economic market forces like supply and demand (a.k.a. biological markets: Noë and Hammerstein 1994). For example, males start entertaining affiliative relationships with females only when they are in estrous, and their investment in that female (e.g., the amount of time they groom them) depends on how many other females are in estrous (supply) and how many other males are interested (demand). Nevertheless, not all relationships follow such patterns. Some relationships remain stable over long periods of time, and these are what we call friendships, at least in humans. However, not only humans have such long-term stable affiliative relationships with others, and by now we know that, for example, chimpanzees can have stable friendships that last at least 10 years (Mitani 2009), and similar patterns have been observed in other primates, but also in elephants (Moss et al. 2010), dolphins (Connor et al., 2000), and several bird species (Bugnyar and Massen 2017). With evidence accumulating that animals do not merely have short-term goal-orientated relationships but also show long-term stable relationships, by now the term animal friendship has been accepted in the academic world (e.g., Seyfarth and Cheney; 2012).

## The Adaptive Value of Friendships

If these enduring friendships are not contingent on current needs, why do we humans and all those

other animals nonetheless entertain such costly long-term investments? A common answer to that question is that a friendship is rewarding in itself; i.e., we experience joy when spending time with friends. Indeed, such emotional responses to proximity to friends can easily be detected, yet from an evolutionary point of view such endorphin peaks do not constitute any fitness benefit (i.e., ultimate causation), but instead provide “merely” the system (i.e., proximate causation) that entices us to form such friendships (c.f. Tinbergen 1963). However, for a behavior like forming and maintaining friendships to evolve it should also have direct (i.e., an increase in survival/longevity and/or reproductive success) or indirect fitness benefits.

Many of the long-term and stable relationships we observe in both animals and humans alike are among kin; by helping our relatives (i.e., nepotism), we *indirectly* promote the contribution of (part of) our own genes to the next generation (i.e., kin-selection: Hamilton 1964). Nevertheless, some of the friendships we observe among humans and other animals are with unrelated conspecifics, or even with individuals of a different species (e.g., human bonds with their dogs), and recent research has elucidated that those friendship also have fitness benefits. In fact, having friends is shown to increase people’s odds of survival by an equal amount as quitting to smoke does (Holt-Lunstad et al. 2010). In non-human animals having friends may be paramount to, for example, surviving a harsh winter (MacFarland and Majolo 2013) or to gain access to mating opportunities (Schülke et al. 2010). Indeed, in the last decade, evidence for fitness benefits of friendship has been accumulating; be it increased access to food or mates, or protection for both the animal itself or its offspring against extreme weather conditions, predators or aggressive conspecifics. Moreover, this evidence does not just include studies on humans and other primates, but encompasses a range of species including, for example, horses, elephants, hyraxes, dolphins, hyenas, kangaroos, but also birds like, for example, geese and ravens.

## Cooperation

Many of the fitness benefits related to friendship arise through cooperation. For example, animals may cooperate while hunting, thereby gaining access to high-value food sources, or team up to fight conspecifics in competition over resources, be it food or mates, or to fend off predators or aggressive conspecifics. Long-term studies on a range of species have now shown that it is specifically friends that form such alliances and support each other in conflicts (e.g., Schino 2007). Additionally, several behavioral experiments testing cooperation in a range of species have shown that the strength of the social bond is indeed the main predictor for success in such cooperation tasks, and that, if given the choice, animals prefer to cooperate with friends rather than with just anybody (e.g., Asakawa-Haas et al. 2016). Relying specifically on friends while cooperating may be beneficial as your long history with them makes them more predictable and trustworthy. Consequently, not only humans but also, for example, chimpanzees place greater trust in their friends than in non-friends (Engelmann and Herrmann 2016).

Trust in a partner becomes really important when the benefits of cooperation are not acquired at the same time for both partners; i.e., when one individual helps another now, and the other reciprocates that help when the former individual needs it at a different point in time (i.e., reciprocal altruism: Trivers 1971). Such an interaction carries a form of uncertainty because you do not know if the other keeps up to his/her part of “the deal,” as there is the possibility of freeriding. To prevail, one needs to keep track of such cheaters and not interact with them anymore and only maintain interactions with those that reciprocate. However, the cognitive requirements underlying such tit-for-tat reasoning have been subject of debate (e.g., Brosnan and de Waal 2002), as many animals are considered unable to keep track of everything given and received from all their group members, especially when living in large groups. Whereas humans may be able to do so (which can be debated considering the large-scale societies we live in), in fact, humans tend not to revert to such “calculated reciprocity” (see Brosnan and de

Waal 2002) in their everyday interactions. Instead, in their decisions on whether to invest they rely on the feelings they have for a certain interaction partner. Such emotionally based reciprocity (Schino and Aureli 2010) relies on series of interactions with a partner to create such specific emotions and is not necessary contingent on the short-term but rather on the long-term. Whereas such a system may be exposed to short-term inequality, it is constantly updated, and that friend that never buys a round of drinks may slowly become less of a friend and consequently will also receive fewer drinks from his/her “friends” after a while. Observational data on exchange patterns among a variety of species shows that also among non-human animals, these exchanges are mostly not contingent on the short-term but rather on the long-term. Moreover, it has been shown experimentally that animals base their decisions of, for example, food sharing on the more long-term qualities of a relationship, rather than on immediate reciprocation.

## The Requirements of Friendships

In contrast to when we interact with strangers, when dealing with friends we do not seem to actively keep track of what is given and received (Massen et al. 2010). Consequently, having friends may sound like one of the simplest things there is. Nevertheless, creating and maintaining such unique social bonds does require some cognitive skills and some biochemical regulations. However, by now many studies have shown that not only humans have the cognitive requirements for friendships, and moreover, that the biochemical mechanisms that allow for such relationships seem evolutionary old and are shared among many animal species (Brent et al. 2014).

### Cognitive Requirements

To have friends, you need to know who they are; i.e., distinguish them from other individuals. Individual recognition may seem a given, but not all animal species have it, or at least for some there is no proof so far (Sheehan et al. 2014). Nevertheless, it is widespread in the animal kingdom with examples in both vertebrates and invertebrates,

which are using either visual, vocal, or olfactory cues or a combination of those to distinguish individuals from each other (Tibbetts and Dale 2007). Next you need to understand your relationship with that other and, if separated for a while, also remember the nature of that relationship. Because it could be harmful if you start treating your former enemies as friends, many species do indeed remember and understand the nature of their relationships with others.

Besides knowing who your friends are, it may also be beneficial to know who the friends of your enemy are. For example, you don’t want to pick a fight with someone, if at that moment that individual has multiple friends standing next to him/her. Thus, to have an understanding of the relationships of others can be very important for surviving in large social groups, and it is the need for such social intelligence that is hypothesized to be the driving force in the evolution of large brains (Byrne and Whiten 1999). Having such knowledge may be particularly beneficial if used to ones own advantage in a Machiavellian way (see ► “Machiavellian Intelligence”). For example, ravens seem to monitor the affiliative relationships of their conspecifics, and when they notice that others attempt to become friends and thus potentially form a powerful competitive alliance, they intervene in the affiliative behaviors of those two birds thereby preventing them from forming that bond (Massen et al. 2014).

### Biochemical Mechanisms

As mentioned before, friendships seem to be regulated, at least partly, by emotions. The emotions involved in friendship do not only have a behavioral and cognitive component, but also, like any emotion, require a certain physiological infrastructure. Not surprisingly, oxytocin (which has sometimes been dubbed the “love hormone,” but see De Drue and Kret 2015) does seem to play a major role. Oxytocin, mesotocin (the oxytocin homologue in amphibians, reptiles, and birds), or isotocin (the oxytocin homologue in fish) promote and facilitate different aspects of social bonding like for example trust and cooperation, in both humans (De Drue and Kret 2015) and other animals (Young and Wang 2004). Additionally,

$\beta$ -endorphins, which are involved in the reward system, are released during certain social behavior. As these  $\beta$ -endorphins induce positive affect, this mechanism may be a crucial driving force in the initiation of friendships (Keverne et al. 1989). In contrast, a lack of social contact may be stressful (e.g., Stocker et al. 2016), and the avoidance of associated high cortisol levels, may form an alternative reason for the initiation of friendships. Finally, a combination of different biochemicals and their interactions with each other play important roles in, for example, the perception of social stimuli and social memory but also in aggressive behavior (see Brent et al. 2014 for a nice overview).

## The Development of Friendships

Relatively little is known about how friendships start and develop over time, as it is rather difficult to pinpoint the exact start of “a series of interactions” and to check whether there is actual partner choice at play. Many social relationships seem structured by the society the animal lives in. For example, in societies that are based around matrilineal friends are often kin. Also, just by avoiding aggression, hierarchical societies are structured such that dominance status leads to spatial centrality in the group (Hemelrijk 2000). Thus, dominant individuals spend most of their time close to each other in the center of the group, whereas more subordinate individuals spend most of their time with other subordinates at the periphery of a social group. As a consequence, many friendships are based on similarities in traits like dominance rank, but also for example age (e.g., Silk et al. 2006). Likewise, having similar interests can influence the spatial structure of a social group in such a way that you end up next to each other. For example, curious individuals are always at the forefront of a population and just by association may become friends (Croft et al. 2009). Alternatively, you may actively choose to spend your time with individuals that have similar interests and or personality. Similarity increases predictability (as you know what you would do in a given situation) and could consequently increase

trust in cooperation. Recent research does indeed show that, like humans, animals choose their friends based on similarity in personality (Massen and Koski 2014).

## Conclusions

After some controversy in the early days of animal cognition and behavior studies, by now the term animal friendship is accepted across the field. Studies on a multitude of species show that animals entertain differentiated relationships with their group members, and like human friendships, the affiliate relationships between animals are not just short term “business deals” but instead can be stable over long time periods.

Friendships of humans and other animals are adaptive as they provide clear fitness benefits, be it survival or increased reproductive success. Most of these benefits are acquired by cooperation, and animals indeed do cooperate more often and more successfully with their friends in comparison to with other conspecifics, and consequently, also seem to actively choose to cooperate with their friends. If cooperation concerns the reciprocal exchange of goods and services, animals, and in particular friends, do not keep an active count of what has been given and received. Instead, they rely on an emotionally based mechanism, in which decisions to give are based on the long-term qualities of the relationship with the interaction partner.

To have friends requires some cognitive capacities. First off you need to be able to recognize and differentiate individuals from each other, and second, you need to recognize and remember the specific relationship you have with certain individuals. Additionally, understanding the relationships of others may also be beneficial when maneuvering in a complex social world. From a physiological perspective, friendship concerns a mix of biochemicals that operate different systems within the brain. And like the cognitive aspects, these systems seem evolutionary old and shared among a range of different species.

Finally, the ontogeny of friendship is relatively understudied, particularly because it is difficult to

observe the actual start of a friendship. Nevertheless, some retrospective studies are showing that many friendships are based on homophily; i.e., love of the same. Friends may be similar with regard to rank or age simply by association. Alternatively, animals actively choose to befriend individuals that are similar with regard to personality, since these are more predictable and may consequently be trustworthier in future cooperation. As the saying goes, it does indeed seem like that “birds of a feather flock together.”

## FSH

David J. Piekarski<sup>1</sup> and Naomi Ondrasek<sup>2</sup>

<sup>1</sup>Psychology, University of California, Berkeley, Berkeley, CA, USA

<sup>2</sup>UC Davis, Davis, CA, USA

## Synonyms

Follitropin alfa; Follitropin beta

## Definition

Follicle-stimulating hormone (FSH) is a glycoprotein hormone that acts primarily at the gonads to regulate multiple aspects of reproductive physiology in both males and females, including gametogenesis, follicle maturation, and steroidogenesis.

## FSH Structure

FSH, and the closely related luteinizing hormone (LH) and chorionic gonadotropin (CG) form a class of hormones called the gonadotropins that

regulate the physiology and function of the gonad. FSH and LH are produced and secreted by gonadotrope cells in the anterior pituitary gland and all gonadotropins are composed of two distinct subunits, an alpha subunit that is common to FSH, LH, CG, and thyroid-stimulating hormone, and a beta subunit that differs among these four hormones and confers specificity of function to each. The alpha and beta subunits are bonded noncovalently and each contain numerous oligosaccharides attached to the amino acid backbones. Different patterns and classes of attached oligosaccharides result in multiple alpha and beta subunit isoforms that differ in circulating half-life, receptor binding properties, and bioactivity (Mullen et al. 2013). These moieties also differ across life-history stages, such as during puberty and pregnancy, resulting in altered FSH dynamics across the lifespan (Mullen et al. 2013).

## Regulation of FSH Synthesis and Release

### HPG Axis

In both sexes, synthesis and release of FSH is tightly regulated by a multi-tiered, negative-feedback system called the hypothalamic-pituitary-gonadal axis (HPG axis). In this system, reproductively relevant information from the brain and periphery is integrated by a population of neurons in the hypothalamus that express the peptide gonadotropin-releasing hormone (GnRH). GnRH is released from axon terminals into the pituitary blood supply to activate gonadotropes that produce and release both FSH and LH into the general circulation. Together, these gonadotropic hormones regulate steroidogenesis – the production of steroid hormones, particularly estradiol and testosterone – and gametogenesis in both sexes. The newly produced gonadal steroids, along with a number of other gonadotropin-stimulated gonadal peptide hormones, feedback to the hypothalamus and pituitary to inhibit further gonadotropin release. This negative feedback system maintains circulating concentrations of FSH and LH appropriate to the animal's life-history stage and reproductive status.

## FSH Function Across Life-History Transitions

Given its critical role in reproductive physiology, FSH production and release tends to coincide with periods of reproductive competence or heightened gonadal steroidogenesis across the lifespan (with the notable exception of reproductive decline/senescence, see below).

### Adulthood

#### Females

FSH is critical for the maturation of female gametes. Prior to ovulation, FSH serum concentrations are high and contribute to recruitment and maturation of a new cohort of ovarian follicles each reproductive cycle (Hall 2016). After ovulation, FSH decreases until it rises at the initiation of the next round of follicular maturation.

FSH also prepares the ovary to initiate and respond to factors regulating ovulation from the mature follicle. Specifically, FSH increases ovarian expression of the LH receptor and aromatase, an enzyme necessary for the synthesis of estradiol. The latter event is critical because elevated estradiol initiates ovulation by stimulating a surge of LH from the anterior pituitary. Thus FSH and LH complement each other to promote normal reproductive competency during female reproductive cycles.

#### Males

FSH, in conjunction with locally synthesized testosterone, helps to initiate and maintain spermatogenesis (Plant and Marshall 2001). FSH receptors are localized to, and induce proliferation of, Sertoli cells that are located within the blood-testis barrier. Each Sertoli cell is responsible for supporting a finite number of germ cells, resulting in a direct relationship between FSH-induced proliferation of Sertoli cells and maximum adult spermatogenic capacity (Liu and Veldhuis 2016). FSH is not thought to contribute directly to testosterone production; however, FSH does stimulate production of estradiol and a complement of proteins that may act locally to regulate intratesticular physiology and steroidogenesis (Gnessi et al. 1997).

### Fetal/Neonatal Period

In placental mammals, the HPG axis is active shortly after birth, resulting in high circulating concentrations of FSH during early infancy. During this time, FSH contributes to proliferation of Sertoli cells in males (Liu and Veldhuis 2016) and supports FSH receptor expression and follicular development in ovarian follicles, both of which set the stage for activation and maintenance of normal reproductive function in adulthood.

### Puberty

During the juvenile period of development, the HPG axis is quiescent and FSH levels decrease to basal concentrations. At the onset of puberty, HPG quiescence declines and FSH concentrations rise in both sexes. The elevation in FSH induces the initial stages of folliculogenesis in females (Hsueh et al. 2015), while in males it initiates sperm production and a second round of Sertoli cell differentiation (Plant and Marshall 2001), which is subsequently maintained by high local concentrations of androgens. Thus, in both sexes the pubertal rise in FSH increases fecundity, coincident with steroid-mediated maturation of pubertal reproductive behavior, and somatic physiology.

### Pregnancy, Parturition, and Lactation

In mammals, normal ovarian cyclicity is eliminated during pregnancy, resulting in a virtually complete decline in maternal circulating FSH and LH for the duration of pregnancy. Upon parturition, FSH concentrations rise and are maintained at normal follicular phase levels. In women, varying durations of lactational amenorrhea may occur; however, FSH continues to stimulate follicular growth during lactation, even though ovulatory cycles are prevented due to decreased steroidogenesis (Velasquez 2006).

### FSH and Fertility: Menopause, Andropause, and Infertility

Some species outlive their periods of maximal fertility, resulting in either reduced fertility or

complete cessation of reproduction with aging. In women, one of the earliest hormonal harbingers of menopause is an increase in FSH, due to the loss of negative feedback that results from decreased ovarian steroidogenesis (Hall 2015). Further decline in circulating gonadal steroids, but maintenance of normal hypothalamic and pituitary function, leads to decreased negative feedback and a chronic ~15-fold increase in circulating FSH after menopause (Hall 2015). Males also experience a decline in reproductive competence with aging, though it is neither as abrupt nor as drastic, resulting in a gradual two- to threefold increase in circulating FSH in elderly men (Snyder 2016).

### Evolution

Glycoprotein alpha and beta subunits arose in early metazoan evolution. However, the FSH beta subunit, marking the origin of FSH, likely diverged from this ancestral gonadotropin sometime during the early evolution of jawed fish, resulting in the presence of an FSH beta homologue throughout jawed vertebrate phylogeny (Kawauchi and Sower 2006).

Within a given species, the FSH beta subunit tends to show low genetic variation, purportedly because its critical role in the maintenance of reproduction places significant constraints on its evolution. Across species, a high degree of similarity in the three-dimensional structure of FSH likely results from the conservation of the locations of cysteine residues and disulfide bridges (Mullen et al. 2013).

In females, the function of FSH has been largely conserved across jawed vertebrates but its role in initiating spermatogenesis is more labile across species. In fish, the FSH receptor is localized to both Sertoli cells and Leydig cells (which are the primary steroidogenic cells of the testis), while in mammals and birds the FSH receptor is localized to Sertoli cells alone (Huhtaniemi 2015). Notably, in fish the FSH receptor binds to both LH and FSH, providing a mechanism by which either gonadotropin may

initiate and maintain spermatogenesis and steroidogenesis in males.

## Environmental Influences on FSH Secretion

In temperate areas, avian and mammalian species commonly display seasonal variations in behavior and physiology that allow them to restrict the production and rearing of young to warmer, resource-rich times of year. During the reproductively inactive period, individuals show cessation of breeding behaviors and maintain low levels of circulating steroid hormones and gonadotropins, as well as regressed gonads (Ball and Bentley 2000). In a taxonomically diverse range of species (including rodents, ungulates, and songbirds), these changes are mediated by the transduction of photoperiod cues to the GnRH system and, in at least some species, the more recently discovered gonadotropin-inhibiting hormone (GnIH) system (Kriegsfeld et al. 2015). Notably, the specific impacts of day length on these systems and the timing of annual reproductive changes can vary considerably across species, depending in part upon whether they are long or short day breeders. However, in general, the reductions in LH and FSH secretion are observed during the non-breeding season and lead to suppressed gametogenesis and sex hormone production (Kriegsfeld et al. 2015).

## Conclusion

Work across many decades has done a great deal to clarify the critical role of FSH in reproduction. However, additional FSH functions may exist. For instance, as recently as 2001, it was thought that FSH receptors did not exist in the brain and that FSH influenced reproductive behavior indirectly via its impact on sex steroid production. However, both FSH receptors and locally produced FSH have been identified in several brain regions and a diverse number of organs and tissues (Harvey et al. 2012), suggesting that FSH

may serve diverse functions across the brain and body that are not directly related to reproductive physiology.

## Definition

Functional genomics is one of the fields of molecular biology that is attempting to make use of the vast wealth data produced by genome sequencing projects to describe genome function.

## Background

Over a decade, several conventional biology methods like Southern analysis, Northern analysis, PCR, RT-PCR, RNase protection assay, and in situ hybridization detecting DNA or RNA that enabled to assess gene expression levels over

a multitude of paradigms including normative conditions, development, experimental manipulations, and pathological states. These well-accepted methods typically quantitate the abundance of individual transcripts or molecules one or few at a time.

Proteomics reveals complex protein expression, function, interactions, and localization in different phenotypes of neuron. As proteomics, considered as a highly complex screening technology, moves from a theoretical approach to practical reality, neuroscientists have to determine the most appropriate applications for this technology. In proteomics, protein fractionation and separation use two-dimensional gel electrophoresis (2-DGE) as well as multi-dimensional liquid chromatography (LC) followed by mass spectrometry (MS). For qualifying relative gene product expression between samples (e.g., two-dimensional difference in gel electrophoresis (2D-DIGE), isotope-coded affinity tag (ICAT) and iTRAQ methods have been utilized. The possible coverage of the proteome has ability to detect unique cell components such as post-synaptic densities and membrane proteins, resource requirements, and quantitative as well as qualitative reliability of different investigative approaches. While there are many challenges in neuroproteomics, this field promises many returns in the future.

Neuroscientists found it challenging to overcome difficulties particular to the research in neuroscience and behavioral genetics, such as limited sample amounts, heterogeneous cellular compositions in samples, and the fact that many proteins of interest are hydrophobic proteins. The necessity of exclusive technology, sophisticated software, and skilled manpower itself is the big challenge.

Developments in high-throughput functional genomic technologies enable the assessment of dozens to hundreds to thousands of genes simultaneously in a coordinated and potentially stochastic fashion (Schena et al. 1995; Lockhart et al. 1996; Brown and Botstein 1999; Eisen and Brown 1999). Transcriptome profiling experiments using microarrays are data-driven approaches with the potential power to uncover

unanticipated relationships between gene expression alterations and experimental manipulations or neuropsychiatric/neuropathological conditions.

Whenever, when we discuss that how the environment, particularly the social environment, does influence brain and behavior of animals, we ask and what are the underlying physiologic, molecular, and genetic mechanisms? The changes in social or physical environment leads to the adaptations by brain and behavior and expressed either as short-term or as long-term modifications in behavioral or physiologic properties in animals. Because living systems depend on their environment, the evolution of environmental adaptability is inseparable from the evolution of life itself (Pross 2003).

To explore and understand the complex relationship between genome and environment, functional genomics approach has been implemented. It determines the genes, under environmental control, which facilitate the study of interrelationship between an individual's gene expression profile and its social phenotype in a given environmental condition. In this chapter we will discuss, how functional genomics played important role in cognition and behavioral aspects of animals. It was outlined the advantages as well as some of the potential challenges of applying high-throughput functional genomic technologies toward a better understanding of neural and behavioral features.

## Introduction

According to EMBL-EBI, functional genomics is the study of how genes and intergenic regions of the genome contribute to different biological processes. Typically it studies genes or regions on a “genome-wide” scale (i.e., all or multiple genes/regions at the same time), with the hope of narrowing them down to a list of candidate genes or regions to analyze in more detail. It describes gene function, gene expression patterns, and control of gene expression of all genes in a genome and their interaction with different

cellular processes and phenotype. It is also helpful in investigation of gene expression change in various diseases or following a treatment.

The goal of functional genomics is to understand the complex relationship between an organism's genome and its phenotype. Functional genomics focuses on the dynamic expression of gene products in a specific context, for example, at a specific developmental stage or during a disease. It focuses on the high-throughput techniques like DNA microarrays at RNA level (transcriptomics), proteomics at protein level, epigenomics at DNA level, metagenomics at metagenome level while metabolomics at metabolite level and mutation analysis to describe the function and interaction of genes. Functional genomics typically utilize large-scale, high-throughput assays like DNA-microarray, RNAi analysis, or proteomics with samples from patients and healthy individuals to measure and track many genes or proteins in parallel. This “genome-wide” approach allows the function of different parts of the genome to be discovered by combining information from genes, transcripts, and protein.

## Functional Genomics in Cognition and Behavior Analysis

Living organisms adapt and survive in varying environments with the ability of their complex survival strategies. Diurnal or seasonal fluctuations of abiotic environmental factors such as temperature, oxygen availability, and salinity affect the life history strategies, physiologies, and behavior of organisms. In humans, social environment is an unavoidable factor deeply influencing the behavior and development of individual. One of the grand challenges in animal biology is to understand the influence of genes on the development of phenotypic and behavioral traits. Just like any other phenotypic trait, behavior is commonly influenced by both environmental and epigenetic factors (Pigliucci 2001). Because of this intricate relationship between genes and environment, the genetics of behavior and of the most common diseases requires the dissection and analysis of complex phenotypes or traits.

In cases where the frequency of the environmental change (the stimulus) is high or when immediate action is required, nervous systems can respond quickly by means of modulation or through learning. Those dynamic changes of the internal state of an animal (e.g., motivation, memory trace) are usually achieved, at least initially, by changes in neural activity and excitability or by endocrine responses.

Short-term changes will then often lead to subsequent changes in brain and behavior (e.g., memory formation) through differential gene expression as well as structural and physiologic changes. Environmental stimuli that are slow or relatively infrequent can alter developmental trajectories and shift neural functioning throughout life history, even in adult animals (e.g., seasonal and use-dependent changes). (See Fig. 1.)

By integrating concepts from neurobiology, ethology, and evolutionary biology with powerful genomic technologies, functional approach facilitates a more comprehensive understanding of the roles that genes and environment play in the dynamic and plastic sculpting of brain and behavior throughout life.

In fact, behavioral genetics has provided us with a wealth of information regarding the roles of individual genes in the implementation of behavior. Genetic and functional genomic studies have already yielded important insights into neuronal diversity and function, as well as disease. The major challenges facing the genetic study of behavior is intricate relationship to dissect and analysis of complex traits involve genetic, epigenetic, and environmental traits whose interactions are often unpredictable.

**Functional Genomics, Fig. 1** Conceptual diagrammatic representation of phenotypic plasticity of brain and behavior (Modified figure referenced from Hoffmann 2003)

One of the most exciting and challenging frontiers in neuroscience involves harnessing the power of large-scale genetic, genomic, and phenotypic data sets and then development of tools for data integration and mining for better understanding of the genetic mechanisms underlying behavior.

The functional genomics revolution allowed neuroscientists to provide a more integrative understanding of nervous system function. It allows the detailed study of individual molecules of interest to an understanding of interacting signaling or metabolic pathways within cells, by combining these data to achieve a systems-level understanding of brain circuit function in health and disease.

Animal's brain is complicated structure with heterogeneous neuronal and non-neuronal cell types with interconnected circuits. The advances in technical and experimental methods for accession of tissues, RNA amplification, and improved downstream genetic methodologies including microarray analysis and RT-quantitative PCR opened the door of informative studies pertinent to understanding brain structure and function thoroughly. However, transcriptome profiling by microarrays having the potential power to uncover unanticipated relationships between gene expression alterations and neuropsychiatric or neuropathological conditions. It also provides an affordable, simultaneous assessment of expression levels of a sample preparation in a single experiment. For example, in the

hippocampus and basal ganglia for a variety of downstream genetic analyses in animal models, including studies of alcohol consumption (Saito et al. 2002), aging (Blalock et al. 2003), amyloid overexpression (Dickey et al. 2003; Reddy et al. 2004), and antidepressant administration (Drigues et al. 2003), microarray analysis has been utilized.

Henceforth, modern functional genomics with the inputs of large-scale high-throughput analysis of gene expression enabled the quantitative assessment of dozens to hundreds to thousands of genes simultaneously in brain regions and individual cell populations. Thus, functional genomics approach facilitates the dynamic measurement of gene products in a parallel manner, coupled with an underlying systems-level knowledge of the organization of these gene products (see Fig. 2).

## Functional Genomics in Psychiatric/ Behavioral Disorders

The complete raw data obtained by high-throughput microarray or mass spectrometry technologies among others permits specialized computational methods for data analysis leading to the development of biomarkers, for example, biomarker discovery for neurological diagnosis and prognosis. By extracting significant genomic and proteomic biomarkers in controlled experiments, one can understand how biological

**Functional Genomics, Fig. 2** Presentation of a potential high throughput framework for functional genomics (Modified figure referenced from Ding and Lawrence 2001)

mechanisms contribute to neural degenerative diseases such as Alzheimer's and how drug treatments interact with the nervous system. The recent development of microarray technologies has made possible the simultaneous measurement of mRNA levels for thousands of genes and a new genomic method termed gene expression profiling. The application of this approach to animal models provides a powerful tool for the discovery of novel genes involved in psychiatric disorders. This approach has an efficiency to complement to another genomic method for gene discovery, positional cloning. Microarray technologies and their application to animal models of bipolar disorder were reviewed. A novel approach termed convergent functional genomics, which integrates gene profiling and positional cloning in order to rapidly identify candidate disease genes, was also described.

One of the difficulties of applying microarray and related genomic studies to neuroscience-based disciplines was that many classes of transcripts as well as individual genes tend to be expressed at relatively low levels (with corresponding low copy number for specific genes). In addition, gene expression patterns, or mosaics, often are cell-type specific and reflect the intricate connectivity of the brain, making global studies of gene expression patterns difficult to interpret, and the relevance of performing these types of studies comes into question (Galvin 2004; Ginsberg et al. 2004).

The power of functional genomics in neuroscience is highlighted by several successful demonstrations of the strength of such methods to identify the molecular basis of neuronal diversity synaptogenesis, disease biomarkers, disease mechanisms and pathways, and the development of user friendly genome-scale resources (Geschwind and Konopka, 2009)

Ayalew et al. (2012) reported regarding translational convergent functional genomics (CFG) approach to identify and prioritize genes involved in schizophrenia.

This study involved gene-level integration of genome-wide association study data with other genetic and gene expression studies in humans and animal models. The polyevidence scoring and pathway analyses, and identified top genes

in brain development, myelination, cell adhesion, glutamate receptor signaling, G-protein-coupled receptor signaling and cAMP-mediated signaling are utilized as key to pathophysiology and as targets for therapeutic intervention.

The top candidate genes for Schizophrenia, obtained from this analysis compared with top candidate genes for bipolar disorder and anxiety disorders from previously done CFG analyses, as well as findings from the fields of autism and Alzheimer. Overall, this work plots the genomic and biological landscape for schizophrenia, leading toward a better understanding of illness, diagnostics, and therapeutics.

Further, translational Convergent Functional Genomics (CFG) approach has been also applied to discover genes involved in alcoholism by using gene-level integration of genome-wide association study (GWAS) data from human and animal model studies.

By taking together, these results suggested that stress-reactive DBP animal model helped to validate and prioritize the key behaviorally relevant genes for alcoholism from the CFG-discovered genes.

These genes fall into a series of biological pathways involved in signal transduction, transmission of nerve impulse (including myelination), and cocaine addiction. Overall, this work provided a better understanding of illness, diagnostics, and therapeutics, including treatment with omega-3 fatty acids.

Also examined the overlapping between the top candidate genes for alcoholism from this work and the top candidate genes for bipolar disorder, schizophrenia, anxiety from previous CFG analyses conducted by us, as well as cross-tested genetic risk predictions. This finally revealed the significant genetic overlap with other major psychiatric disorder domains, providing a basis for comorbidity and dual diagnosis and placing alcohol use in the broader context of modulating the mental landscape.

Levey et al. (2014) studied about bipolar disorder in low mood vs high mood in blood samples from mouse and separately measured whole-genome gene expression differences in blood samples as well as changes in gene expression in

the brain and blood of a mouse as pharmacogenomics model.

The integration of human blood gene expression data with animal model gene expression data, human genetic linkage or association data, and human postmortem brain data has been called convergent functional genomics, especially performing cross-validating and prioritizing the findings.

Out of a list of 11 candidate blood biomarker genes, it was found that 5 genes involved in myelination (Mbp, Edg2, Mag, Pmp22 and Ugt8) and 6 genes involved in growth factor signaling (Fgfr1, Fzd3, Erbb3, Igfbp4, Igfbp6, and Ptpm). All of these genes have prior evidence of differential expression in human postmortem brains from mood disorder subjects. A predictive score of ten top candidate biomarkers (five for high mood and five for low mood) shows sensitivity and specificity for high mood and low mood states, in two independent cohorts. This study suggested that blood biomarkers might offer an unexpectedly informative window into brain functioning and disease state.

## Conclusion

The functional genomic methods permit, dynamic measurement of gene products in a parallel manner, coupled with an underlying systems-level knowledge of the organization of these gene products, has the potential to provide a more integrative understanding of nervous system function. The functional genomics approach has provided the better understanding of the complex relationship between an organism's genome and its phenotype. It focuses on evaluation of the dynamic expression of gene products in a specific context, by determining a specific developmental stage or during a disease.

Functional genomics employs high-throughput or microarray techniques to perform the dynamic studies. A microarray experiment has been thought appropriate but still demands much consideration needs to go into sample size and preparation, tissue and/or cell quality, and, importantly, input amount of RNA that would

likely to be generated. Sample preparation, RNA amplification, array hybridization, and array analysis usually require a long-term commitment; many investigators found out this method is frustrating.

Therefore, it was suggested that a combination of multidisciplinary approaches is ideal for verification and broad application of gene expression level alterations, with the explicit knowledge that the sum of the evaluations may be more informative and reflect the actual biology of the system than an individual method.

The revolutionary techniques of functional genomics permitted neuroscientists to get enhanced integrative understanding of nervous system function. It allows neurologists and behaviorists to thoroughly study individual molecules of interest to an understanding of interacting signaling or metabolic pathways within cells. By combining these data, researchers achieve a systems-level understanding of brain circuit function in health and disease.

## Functionalism

Thomas L. Spalding<sup>1</sup>, Matthew Kostecky<sup>2</sup>, James M. Stedman<sup>3</sup> and Christina L. Gagné<sup>1</sup>

<sup>1</sup>University of Alberta, Edmonton, AB, Canada

<sup>2</sup>St. Joseph's College, University of Alberta, Edmonton, AB, Canada

<sup>3</sup>University of Texas Health Science Center, San Antonio, TX, USA

In this entry, we examine functionalism, which is often proposed as, and taken to be, a proper philosophical underpinning for the study of human cognition. We consider two important points. First, does functionalism actually provide a good underpinning for the study of human cognition? Second, does functionalism serve well as an underpinning when extended to the study of non-human animal cognition? We will suggest that the answers to these questions are no and suggest that there are other philosophical positions that provide a better, more integrated underpinning for the study of both human and nonhuman cognition. In particular, we will suggest that an Aristotelian-Thomistic (A-T) approach, recently proposed in cognitive psychology itself (Spalding and Gagné 2013; Spalding et al. 2014) and within the philosophy of mind (Feser 2006, 2014; Madden 2013), should be explored. We begin by reviewing the history of how functionalism came to be adopted by much of cognitive psychology and then discuss some of functionalism's weaknesses for human cognition. We then attempt to see what it would

---

Portions of this chapter were reprinted, with permission, from Stedman, J., Spalding, T. L., & Gagné, C. L. (2016). Does Functionalism Offer an Adequate Account of Cognitive Psychology? *Journal of Mind and Behavior*, 37, 15–30.

mean to extend functionalism fully to the study of nonhuman animal cognition. Finally, we present a brief argument that the A-T approach might be a better philosophical underpinning for the study of cognition, both human and nonhuman.

Confidence in logical positivism and operationism waned in both philosophy and psychology during the 1960s. At about the same time, psychology experienced the cognitive revolution, which reinstated mental states and processes as central to theory building and explanation. As Levin (2013) points out in her review, cognitive psychologists turned to the functionalist theory of mind as a philosophical underpinning for all aspects of cognition. This interchange produced psycho-functionalism, the dominant subtype of functionalism for cognitive science. As described by Levin:

A second strain of functionalism, psycho-functionalism, derives primarily from reflection upon the goals and methodology of “cognitive” psychological theories. In contrast to the behaviorists’ insistence that the laws of psychology appeal only to behavioral dispositions, cognitive psychologists argue that the best empirical theories of behavior take it [behavior] to be the result of a complex of mental states and processes, introduced and individuated in terms of the roles they play in producing the behavior to be explained. . . . All versions of functionalism, however, can be regarded as characterizing mental states in terms of their roles in some psychological theory or other. (p. 7)

Hence, as Levin sees it, functionalism in all its aspects is intertwined with cognitive psychology at both the philosophical and psychological levels.

## Analytic Philosophy and Functionalism

Analytic philosophy, spawned in Britain as a reaction to idealism, dominates English-speaking philosophy to the present time. As Preston (2007) demonstrates in his review of the history of analytic philosophy, the movement was initiated by Russell and Moore, refined as logical atomism by Russell and Wittgenstein (see Wittgenstein 1922), elaborated by the Vienna Circle as logical positivism (Ayers 1952), seriously questioned by Quine (1951), and later reinvented by Wittgenstein (1953). Preston

characterizes contemporary analytic philosophy, the home of the philosophy of mind, as eclectic and interested in limited metaphysical problems, as still grounded in language analysis and semantics, and as interested in the kinds of thought experiments often used by philosophers of mind. Although current philosophers of mind are split along property dualist (e.g., Chalmers 1996) and materialist (Armstrong 1968) lines, all agree that cognitive processes, from sensation and memory through all of the higher-order phenomena of thinking, reasoning, categorization, planning, etc., can be explained by the doctrine of functionalism. In fact, Chalmers (1996), though a property dualist, asserted this about functionalist cognitive models:

Cognitive models are well suited to explaining psychological aspects of consciousness. There is no vast metaphysical problem in the idea that a physical system should be able to introspect its internal states, or that it should be able to deal rationally with information from its environment, or that it should be able to focus its attention first in one place and then in the next. It is clear enough that an appropriate functional account should be able to explain these abilities, even if discovering the correct account takes decades or centuries. (p. 31)

In her review, Levin (2013) points out that functionalism has antecedents (e.g., Wittgenstein 1953) but emerged as a definitive philosophical position in the last 35 years of the twentieth century. Feser (2006, Chap. 3) provides a brief and readable explanation of how functionalism developed in response to problems with other strictly materialist philosophies, such as philosophical behaviorism and identity theory. Several major strains of functionalism developed: machine functionalism, psycho-functionalism, and analytic functionalism. So, far from being monolithic, functionalism itself is divided, with arguments in favor of and attacking the various strains.

Machine functionalism was the first of the three developed and appeared to answer a number of problems with behaviorism, for example, critiques pointing out that behaviorists seemed to undervalue internal mental states, such as beliefs and desires, when those constructs contributed implicitly to their theories. Machine functionalism postulated that any “mind” can be regarded as a

finite digital computer, one that receives inputs (14), while in a certain state (S1), goes into other states (Sx), and produces output (0). The person with a mind is viewed as a probabilistic automaton, so for each state and sets of inputs, the machine (mind) will enter a subsequent state and produce output according to certain probabilities. These internal mental states were called representations, and the nature of these representations was and is disputed. Over time, early machine functionalism's ties to a "machine table" or program came to be seen as inadequate. However, the basic idea involving inputs, lawful interactions of internal states, and final outputs has been retained in later functionalist approaches.

Psycho-functionalism is closely tied to the emergence of cognitive psychology in the late 1960s and maintains that mental states and processes are entities (constructs) that are defined by the role they play in cognitive psychological theories. They may be tied to brain structures and processes, but this is not a requirement. However, there does seem to be a trend toward attempting to ground these constructs in neuroscience (see Stedman et al. 2009). These constructs can include mental states and processes easily identified with common sense (folk psychology) or can go beyond common sense to incorporate more refined constructs identified by laboratory findings, thus replacing folk psychology constructs.

Analytic functionalism (e.g., Armstrong 1968) asserts that all mental states, such as pain, hunger, belief, desire, consciousness, and so on, are constituted by their functional role, that is, to quote Chalmers (1996): "On this view, a mental state is defined wholly by its causal role: that is in terms of the stimulation that tends to produce it, the kind of behavior it tends to produce, and the way it interacts with other mental states" (p. 14).

In spite of these different forms of functionalism, advocates of functionalism hold for the following commonly: (a) functionalism offers a comprehensive ontological account either of all mental states or at least the psychological portion of mental states but not the phenomenal (Chalmers 1996); (b) some mental states, according to Chalmers and others, are primarily psychological and are fully accounted for by

functionalist ontology, including learning, memory, categorization, perception, and higher-order cognitive processes; and (c) some mental states, such as belief, desire, and hope, are referred to as intentional mental states in that they refer to something about the world. Many functionalists regard these states as primarily psychological and, hence, fully accounted for by functionalism. Chalmers (1996) views mental states as mixed. However, whatever in these states is psychological, he asserts, can be accounted for by a functionalist ontology.

As mentioned above, the models of cognitive psychology rest on functionalism as a philosophical foundation, specifically psycho-functionalism. Hence, cognitive psychology, via psycho-functionalism, is subject to all the ontological strengths and weaknesses of analytic functionalism.

Contemporary cognitive psychology theories are grounded in psycho-functionalism, expressed as models and/or mechanisms: for example, perceptual binding, working memory, category formation, and so forth. Some theories incorporate brain structures and processes and others do not. All postulate multiple, interacting mental states and processes that play definite roles in the theory. All are grounded in stimuli at the beginning and behavioral outcome at the end. Various psycho-functional cognitive theories compete, and their truth claims are established by empirical observations.

For example, consider the exemplar model of concept formation. The exemplar model claims that category (concept) formation occurs when people compare new information to exemplars stored in memory. This version of concept formation states that exemplars are learned through repeated presentations and naming of category members and the repeated naming allows the pairing of a common name with a set of exemplars, which in turn allows generalization over those exemplars when the name (or other similar cue) is presented. The exemplar model requires a number of psychological constructs: sensation, perception, learning (of exemplars), many constructs in the area of memory and recall, some mechanism accounting for comparing new stimuli

to exemplars, and an account of language to perform the response. Because cognitive psychology is increasingly linked to neuroscience, interactions with brain structures must also be factored in. Similar examples could be offered for all content areas of current cognitive psychology, and psycho-functionalism is expected to serve as the ontological and epistemological underpinning for all of cognitive psychology.

### **Problems with Functionalism as a Theory of Human Cognition**

As mentioned earlier, both property dualist and materialist philosophers of mind agree that functionalism is sufficient to account for all the “psychological” components of cognitive psychology. However, functionalism, as a philosophical position, has been challenged by philosophers of mind almost from its inception. Two of these objections will be presented in some depth.

A general objection to functionalism, well known in the philosophy of mind, is the “damn/darn problem,” brought forth by Block and Fodor (1972). Their objection lies within the broader theory of mental holism, which claims that the meaning of a belief (or a sentence expressing that belief) is determined by its place in a network of beliefs (or sentences) making up a whole theory or even a group of theories. They point out that a functional account of mental states must take into consideration any difference in stimuli or responses. Joe smashes his finger in the door and says, “Darn”; Clyde smashes his finger in the door and says, “Damn.” We have two equivalent stimuli but different responses. However, functionalists claim that outputs are related to all or many of the agent’s internal mental states, so two people who have pain but produce different outputs must share little, if any, common mental states. But this conclusion appears absurd. Hence, Block and Fodor believe that functionalism leads to an extreme and undefendable version of mental holism.

This critique is also important in that one of the presumed advantages of functionalism was that it would allow one to avoid the type/token problems

that arose in identity theories. In particular, a problem with identity theories is that if the mind/thought is taken to be identical to the brain/brain state, then there must be lawful relations between given brain states and thoughts, but there seem clearly to be logical relations among thoughts, but only physically (efficiently) causal relations among brain states. This difference calls into question rather strongly the whole notion of identity between brain states and types of thought. Functionalism works around this problem by defining states with respect to their functional (including logical) relations to other states. However, if, as Block and Fodor (1972) claim, differences in response (including between individual tokens of a particular type of thought) dictate large differences in mental states, the mental holism implied by this removes this purported advantage of functionalism. In short, functionalism does not avoid a similar kind of problem as that identified in identity theories.

A second, and perhaps more damaging, critique asserts that functionalism, as an ontological claim, is trivial, that is, that functionalism’s internal structures (constructs), anchored by stimulus inputs and behavioral outputs, are not unique but can be present in many complex and less complex systems. This criticism has been stated recently by Godfrey-Smith (2008). These arguments all point out that the functionalist realization of a complex mental system is present when the set of mental states maps or corresponds to physical states of the system. These systems are known as combinatorial state automata (CSA) and can occur in a large number of formats, including a properly manipulated bucket of water! Godfrey-Smith (2008) asserts the following:

If a normal human’s functional organization over some interval is represented by a CSA, then our designer could build a transducer device that perturbs the bucket of water in specific ways in response to every possible sequence of inputs that a human might receive, and another transducer device that maps the water’s responses to appropriate behaviors. So a bucket of sea water could act as control system for a humanoid robot, provided that our designer was extraordinarily knowledgeable about the object’s contingency tree and skilled in the building of input and (especially) output transducer devices. (p. 23)

The triviality argument, as mentioned, is very complex, and only this brief sketch will be presented here. It is important to recognize, however, that the import of the critique goes beyond the fact that it seems to lead to strange outcomes in which a bucket of water might have a mind. In particular, the issue is that if these kinds of arguments go through, then there is no guarantee, in functionalist terms, that any mental or intentional state actually bears the meanings that we ordinarily assign to them (see, e.g., Madden 2013, Chap. 5). In sum, there is a real possibility that a consistently functionalist account of thought collapses upon close inspection (see also Feser 2006). For example, functionalist treatments of intentionality tend to lead to a denial of, or eliminative reduction of, intentionality. But the functionalist treatment itself is presented and argued for in intentional terms. Similar problems arise in functionalist treatments of logical reason and other topics.

Other general objections to functionalism include how to characterize the inputs and outputs of a functional system (Block 1990), problems in accounting for what appear to be the causal effects of our mental states (Kim 1989), and introspective belief (Armstrong 1968). All of these objections and more have been put forward, many from functionalism's early days. In summary, functionalism as a philosophical ontology has met with serious objections. It should be noted that these objections apply to all functionalist positions, including psycho-functionalism and analytic functionalism.

Within cognitive psychology, functionalism has often failed in the task of theory building and theory discrimination. A recent example of this failure was presented by Spalding and Gagné (2013). They pointed out that none of the three predominant models of concept formation (exemplar, prototype, and theory-theory) has emerged as superior, and all have approximately the same amount of empirical support (this problem occurs in many areas of psychology). In fact, they note that recent studies of psychological essentialism, generics, K-properties, and perceptual symbol systems/embodied concepts challenge the validity of all three probabilistic models mentioned above.

It should be noted that all three theories of concept formation meet the criteria demanded by functionalism. All commence with stimulus conditions, postulate interacting internal cognitive constructs, and produce behavioral outcomes. However, years of research have not led any of the three theories to dominance. In fact, Spalding and Gagné (2013) made this comment about the current state of affairs:

Given the diversity of representations and processing systems suggested by recent research results, it is unclear whether there can be a theory of concepts at all (e.g., Machery 2009). How can concepts be both essentialist and yet not involve necessary and sufficient features?... How can they be both sensory-based and abstract/universal? (p. 71)

Hence, we see that this level of theory building and theory discrimination has failed. Of course, it is possible that there will be a new, functionalist-based, theory that will account for human concepts, though Machery (2009) makes a strong case that this is unlikely. However, this conspicuous failure can also be taken to suggest that a more fundamental re-thinking of concepts is in order, and, since failure of theory discrimination is common in most areas of cognitive psychology, perhaps functionalism is simply not up to the task of theory building.

## Functionalism and Animal Cognition

Given that philosophical functionalism arose in the first instance as a way of understanding what constitutes mental states, it is unsurprising that its primary application was to human cognition. Interestingly, in the wake of the "cognitive revolution" in psychology, research in animal cognition took on much of the vocabulary and the theoretical method of human cognitive psychology, with a move away from "pure" behavior and toward the study of memory, perception, etc., in nonhuman animals. In particular, much work on animal cognition took on functional analyses of processes presumed to intervene between stimulus and response, in much the same way as seen in the so-called cognitive revolution. Interestingly,

although animal cognition work took on the vocabulary and theoretical method associated with human cognition, it is unclear that it truly took on the notion of functionalism as a philosophical underpinning. It is unclear to what extent work in animal cognition generally claims that there are “mental states,” and if there are, it is unclear to what extent those mental states are actually constituted by the states’ position in the functional chain (note that it is this quite radical claim that mental states just are the functional connections that makes functionalism the kind of thing that could claim to serve as an account of mental states, philosophically). To our knowledge, there is no existing, full-scale exposition of philosophical functionalism with respect to nonhuman animal cognition.

Lacking an existing clear statement of how functionalism can serve to underpin research on animal cognition, we will attempt to describe how functionalism might be extended from human cognition to nonhuman animal cognition and then to evaluate the resulting construct in terms of whether it provides a convincing account of the relationship between human and animal cognition. As noted above, we find functionalism lacking in its ability to truly undergird the study of human cognition, but the ability to have a single philosophical underpinning (even with some weaknesses) that could profitably be applied to both human and animal cognition would be a boon to psychology as a whole, and this could outweigh functionalism’s weaknesses (at least in the absence of more effective competitors).

We begin considering the extension of functionalism from human to animal cognition by noting that the functionalist is more or less required, by the internal logic of functionalism, to hold that animals have mental states and that those mental states just are functional relationships. That is, because the functionalist holds the highly abstract view of what constitutes mental states (input, state transformations, output) described above, any system having such characteristics (or analyzable into such characteristics) is more or less compelled to have mental states in the functionalist’s view. As noted above, any properly constituted functional system (whether human,

animal, computer, or whatever) thus has “mental” states. So the simplest approach to functionalism and animal cognition is just to say that both human and nonhuman animals have mental states constituted by the functional relationships among those states.

There are both strengths and weaknesses to this extension of functionalism. On the one hand, we have, potentially, a unified underlying philosophical approach that accounts for both human and nonhuman animal cognition. This would, certainly, be an admirable outcome. On the other hand, all the weaknesses of functionalism for human cognition would seem to extend to animal cognition as well. Furthermore, this simplistic extension would seem to require a completely continuous relation between the abilities of nonhuman animals and humans (and, indeed, among all of the nonhuman animals). Functionalism, as such, appears to provide no help in understanding the relationships among the differing abilities of different species (or for that matter, the common abilities of different species), making it, perhaps, not a particularly helpful philosophical underpinning for comparative psychology’s concerns. Finally, it is unclear whether functionalism actually adds anything to the understanding of animal cognition. Recall that functionalism arose specifically as a way of thinking about mental states in humans because those mental states had shown themselves to be resistant to other philosophical accounts (see, e.g., Madden 2013). But there is a real question about the extent to which there is a need for such an approach in order to understand the cognition of nonhuman animals, and further there is a real question about whether it is appropriate to extend intentional notions such as beliefs or hopes to nonhuman animals, even if such notions are appropriate to humans (which is, of course, a question of its own).

In short, the study of animal cognition reveals interesting and principled continuities and discontinuities of behavior and abilities among various species, including in comparing many of those species to humans. While it is certainly possible to extend functionalism from human cognition to nonhuman animal cognition, it is unclear what benefits this extension actually provides, as it

does not seem to offer a clear way of understanding any of the seemingly principled continuities and discontinuities of abilities among the various species. Of course, as we said above, we do not know of any fully developed, clear version of functionalism that has attempted to cover the broad field of animal cognition, so it is certainly possible that such a version could be developed. However, given the concerns we have raised about functionalism as a philosophical underpinning for human cognition, we wish now to suggest an alternative approach that might have more promise.

### The A-T Alternative

As mentioned in our statement of purpose, both philosophers of mind and psychologists have recently proposed Aristotelian-Thomistic alternatives to functionalism. We will consider philosophers of mind first. Madden (2013) has written a thorough review of the major approaches to the philosophy of mind, including functionalism. In fact, he is rather enthusiastic about functionalism, as noted in the following quote:

Functionalism is a powerful theory. It seems to provide an account of psychological states without even a hint of anything left to be explained by supposed nonphysical states, while at the same time allowing for mental causation without raising problems of mind body interaction. . . It is, whatever its vices, a very good idea. (p. 131)

Although Madden concedes that functionalism has many merits, he argues that its shortcomings outweigh its merits as a philosophy of mind. His arguments against functionalism are those covered in the previous section, plus issues regarding intentionality, beliefs, and thoughts in general.

As an alternative, Madden proposes Aristotelian-Thomistic hylomorphic theory as applied to human and animal sensory and cognitive processes as the best solution to the observed phenomena of mind. His argument for this position is indeed complex and is marshaled against materialist positions, property dualism, and substance dualism; all fail as explanatory systems for mind. For the purposes of this essay, we will not

present any further detail regarding these purely philosophical arguments raging among the philosophers of mind but will leave it to the reader to investigate the arguments in the works cited below (As mentioned in our statement of purpose, both philosophers of mind and psychologists have proposed an Aristotelian-Thomistic (A-T) account as an alternative to functionalism. Readable recent descriptions of A-T approaches to metaphysics (Feser 2014), philosophy of mind (Feser 2006; Madden 2013), and other specific relevant topics, such as induction (Groarke 2009) or essences (Oderberg 2007), as well as overall systematic descriptions of Thomistic philosophy (e.g., Feser 2009; Stump 2003), and older descriptions specifically relating to the application of A-T ideas to philosophical and experimental psychology (e.g., Maher 1909), are available. Feser (2014) is particularly interesting in the current context as he takes a compare/contrast approach with many recent developments in analytic philosophy.).

Returning to functionalism's adequacy as an account of cognitive psychology, we have seen that functionalism has deficits as an ontological system. These deficits also apply to functionalism as an underpinning for cognitive psychology. Recognizing problems with functionalism and particularly incoherence in cognitive psychology's account of concept formation led Spalding and Gagné (2013) to propose an Aristotelian-Thomistic alternative model to account for concept formation. At about the same time, Stedman (2013) published a paper demonstrating parallels between modern cognitive psychology and neuroscience and Aristotle's hylomorphic theory. He showed that these parallels exist at all areas of interest to cognitive psychology and neuroscience, including sensation, perception, memory, and higher-order cognitive functions, such as concept formation, theory of mind, reasoning, and so forth.

The details of the A-T model have been elaborated in three recent publications (Spalding and Gagné 2013; Spalding et al. 2014; Stedman 2013) and so will be outlined here only briefly and mostly in order to shed light on how the A-T model presents animal cognition, especially

so-called “higher animals” with complex cognitive lives like wolves, cats, horses rather than, say, sponges, or oysters. In the A-T framework, human and nonhuman animal cognition are fundamentally similar, at least until concept formation is accounted for. Sensory cognition in both humans and nonhuman animals commences with the sensation of particular objects in the environment. Importantly, this account of cognition is conditioned by certain metaphysical commitments, especially that objects in the environment are composed of form and matter, which are correlates to the actuality and potentiality of a thing. Thus, the form of a thing, which is paramount in the account of cognition, is a way of speaking about its actuality, i.e., what the thing is currently doing.

Now, in sensation, the form of the object is received by the appropriate sense organ(s) and is then communicated to the “internal senses” via the production of a “phantasm.” The phantasm is a sort of internal image of the externally sensed object (the technical A-T language here is that the phantasm has the “form” of the external sensed object but not its matter), and these internal senses deal with phantasms in various interconnected ways. On Aquinas’ account, there are 4 internal senses: (1) the “common sense,” which allows for the subject to distinguish between what is presented through different senses and to be aware that external sensing is occurring; (2) the “imagination,” which is the “storehouse of forms” and allows for the animal or human to recall things when the object is not actually present and, in humans, allows for the mental combination and separation of sense images to produce fictional objects; (3) the “estimative sense,” which is called the “cognitive power” for humans (the estimative sense in animals is instinctive and what allows animals to pursue or flee or ignore an external object; in humans, this internal sense compares individual intentions in various sorts of deliberation); and (4) the “memory,” which retains intentions that are held by the estimative/cognitive power. Aquinas says that these internal senses occur in an organ in “the middle part of head,” i.e., the brain.

As noted, sense cognition for humans and non-human animals are fundamentally similar: there is a thing in the external world that is sensed and then communicated internally. Through various internal powers, which are basically the same in humans and nonhuman animals, these sense images are unified into a holistic experience, and those images can be recalled, manipulated, and are the means by which the animal navigates the world. Unlike the functionalist model, cognition in the A-T model does not simply break cognition down to a description of inputs and outputs, but is an internalization of exterior objects. This internalization is not the “representation” of some early modern thinkers, in which the representation is a sort of degraded copy of the external thing, but the formal existence of the exterior thing existing internally or mentally. Thus, the basic metaphysical structure of the external world – wherein objects are composed of form and matter – is reflected internally but only at the formal level. The matter is left out in the external world, while the form is propagated via sense organs and internal senses internally. The result is a particular intention of the external object.

It is axiomatic for the A-T framework that sensation is always of particular things, whereas understanding, via concepts, reaches to universals. As such, the sensory process just explained only touches upon particulars and the sensory process only has particular intentions. As such, on the A-T model, nonhuman animals only ever sense and cognize particulars. So-called “higher animals” can, in a way, recognize an external object as being a member of a class, but this is accounted for through the estimative power, i.e., instinct. Thus, if a wolf falls into the field of vision of a sheep, the sheep immediately recognizes a threat and will pursue an instinctual course of action. This response does not cognize the wolf as a wolf, but as a threat (whereas the converse will hold for the wolf that sees a sheep, which will be seen as an object of desire). This is the closest to some sort of universal cognition that the A-T model will afford animals, for at this point the cognitive story for humans and nonhuman animals diverges, and the A-T model will turn to account of concept formation by way of a process

of abstraction, which accounts for the move from a particular to a universal intention or concept.

It is beyond our current purposes to explain in detail the complex process by which concepts are formed on the A-T model, for that process speaks to what is conceived as a conceived as a uniquely human process. It should be noted, however, that Spalding and Gagné (2013) surveyed several varieties of concepts research and showed that the results, though seemingly completely incompatible from the viewpoint of modern concept theories, all appear to be at least compatible with, and in most cases directly expected by, the A-T view of concepts. On the basis of this strong correspondence between the A-T view and the empirical results, Spalding and Gagne suggest a serious investigation into the A-T view as a possible high-level framework within which the scientific investigation of the psychology of concepts can proceed. Most importantly for the present purposes, Spalding and Gagné's presentation of the A-T view should be taken as a kind of existence proof that an A-T approach is compatible with modern scientific psychological research (see also Gagné et al. [in press](#), for an example applying an A-T approach to a specific experimental research program within the field of concepts research).

## Functionalism, the A-T Model, and Animal Cognition

Animals have sensation, perceptual organization of that raw sensation, and memory. They can learn and many assert that they also have "higher-order" cognition that parallels human thought, reasoning, and problem solving, at least to a degree. As Aristotle noted, a living organism's abilities are known by observing its behaviors and certainly animals, especially primates, manifest these behaviors. It is not the purpose of this essay to debate the "higher-order" cognitive abilities of human vs. animals (see George 2003, for a thorough discussion of this topic). Our task is to consider whether the A-T model is superior to functionalism in accounting for animal cognitive behaviors.

The shortcomings of functionalism, as a general theory and as a metatheoretical underpinning for psychology at every level, have already been discussed and will not be repeated. The A-T model offers an explanation of all animal cognition based on an analysis of the external and internal senses. The external senses are those we are all familiar with, such as hearing and sight, and there is a vast animal psychology literature investigating these phenomena. The internal senses, discussed previously, account for perception, memory, and "higher-order" cognitive events in animals. A-T theory holds the following: (1) these abilities are brain based, (2) these abilities are shared by humans and animals, and (3) these four internal senses can explain all of animal behavior, including what many believe to be acts of reasoning and problem solving in mammals (see Cates 2009; George 2003, for an elaborate discussion of these issues).

Some may react to the presentation above and conclude that the A-T model and the functionalist model are very similar in their accounts of animal cognition, such that one is no better than the other. Indeed, both depend on external sensory input; postulate mechanisms to account for sensory integration, memory, and such; and look at behavior outcomes for proof. We claim that the A-T model is superior because it offers a better and more detailed account at the animal level and an integrated account of both animal and human cognition.

## Conclusions

The major outlines of A-T and functionalism as ontological and epistemological systems have been presented here and in the recent publications mentioned above. We have also considered some of the philosophical strengths and weaknesses of both functionalism and the A-T model. While much thought has been devoted to philosophical critiques of both systems, we have not attempted to summarize that material in a few lines. We simply assert that, in a head to head comparison, the A-T hylomorphic model is better than functionalism as a scientific realist account of human

and animal cognition. Arguments for this assertion are found throughout this essay, in the three recent publications cited (Spalding and Gagne 2013; Spalding et al. 2014, and Stedman 2013) and specifically in Stedman et al. (2016). Functionalism claims to be an adequate ontology to explain all cognitive events from sensation to all higher-order cognition. However, as pointed out above, functionalism has been seriously challenged as an adequate general ontological theory. Spalding and Gagné (2013) and Stedman (2013) both make a reasonable case for A-T ontology as a meta-theory that provides at least as good a philosophical underpinning for cognitive psychology as functionalism does, in that (a) the A-T approach is compatible with the existing cognitive psychology research results and (b) the A-T approach is capable of accounting for many aspects of the concepts literature that are deeply surprising if one takes a functionalist approach. Finally, we have shown that there are also philosophical reasons to prefer the A T approach and have shown that some of the common objections to such an approach are misguided and often based on a misunderstanding of the A-T approach.

## Fungi

Neelabh<sup>1,2</sup> and Karuna Singh<sup>3</sup>

<sup>1</sup>Department of Biotechnology, SR Institute of Management and Technology, Lucknow, Uttar Pradesh, India

<sup>2</sup>Department of Zoology (MMV), Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

<sup>3</sup>Department of Zoology (MMV), Banaras Hindu University Varanasi, UP, India

Fungi are present in almost all habitats. At present about 99,000 known species of fungal organisms, including yeasts, rusts, smuts, mildews, molds, and mushrooms exist on earth. They are

eukaryotic organisms which have been placed in a separate kingdom from “Animals” and “Plants” (Ruggiero et al. 2015). Fungi are only second to the plants with respect to biomass on land, and unlike plants, are devoid of chlorophyll. They are more closely related to animals than plants. Most peculiar feature about the fungi is their cell wall which is composed of glucan or chitin, unlike cellulose in plants (Bowman and Free 2006). The difference between chitin and cellulose sub-unit has been shown in Fig. 1 (<http://www.easybiologyclass.com/kingdom-fungi-general-characteristics-key-points-with-ppt/>) and the image of the fungal cell wall has been provided in Fig. 2 (<https://byjus.com/biology/fungal-cell-wall/>).

Fungi are aerobic in nature depicting both sexual and asexual reproduction. Unlike plants, they are heterotrophs which have the ability to form diffuse bodies comprising of an extended network of very narrow, tubular, branching filaments termed as hyphae. These filaments secrete enzymes and also absorb the food at their growing tip. They are chiefly found growing on dead and decaying material. Some of them are useful as food, source of medication, and recycling, mycorrhizae and plant growth, and others are less desirable, such as mold on food or spores that cause diseases (Kendrick 2011).

Fungi can exist in two forms: yeasts and molds. The important identifying characters of yeast are that they are single, small, and oval cells, whereas hyphae are the characteristic feature of the mold form. Apart from this, another group of fungi exist which has the ability to exist in both form and require a stimulus such as temperature to switch

**Fungi, Fig. 1** Structural difference between the chitin and cellulose present in fungal and plant cell wall respectively

**Fungi, Fig. 2** Structure and composition of the fungal cell wall

between the two forms (McGinnis and Tyring 1996; Gow et al. 2002).

Fungi have three major roles to play in the environment: (1) as saprobes, (2) as pathogens/parasites, and as (3) mutualistic symbionts. In the terrestrial ecosystem, the saprophytic fungi play a vital role in order to decay the dead material. Plant debris comprising of lignin, cellulose, and animal debris constituting of chitin and keratin needs to be degraded in order to release the basic constituents back into the biosphere, otherwise due to continuous piling up of the dead material, the soil would become unfertile and impoverished. Next, the fungus also plays the role of a parasite and pathogen. Not all fungi can cause diseases but a few of them can cause serious and fatal infections in both plants and animals. Generally, fungi are opportunistic in nature and infect immunocompromised (suffering from AIDS, undergoing radiotherapy or chemotherapy, undergone a transplant, etc.) individuals (Neelabh and Singh 2018).

Finally, the most interesting aspect of the fungal ecology is the mutualistic symbiosis. Fungi are known to live in close co-operation with a variety of organisms such as cyanobacteria (blue-green “algae”) and chlorophycota (green algae) (in lichens), with bryophytes, pteridophytes, gymnosperms and angiosperms (in mycorrhizae), and with coleopteran, dipteran, homopteran, hymenopteran, and isopteran insects (Read et al. 2000).

## Conclusion

Fungi have multitudinous roles to play in the environment, primarily the role of saprophytes.

They are both advantageous and harmful in many respects. A broad range of their use especially in the field of agriculture and medicine makes them very useful for the mankind but in contrast to this the deleterious effects of some fungi in the storage of food grains and human health can be devastating. However, these ill effects of the fungi can be curtailed to a certain extent if proper storage methodologies are employed and suitable measures regarding diagnosis and treatment of the fungal diseases are executed.

<sup>2</sup>Department of Evolutionary Anthropology, Duke University, Durham, NC, USA

## Synonyms

Center of mass; Duty factor; Footfall; Limb phase; Locomotion; Tetrapods

## Definition

A locomotor pattern typical of legged animals that can be described either by the sequence of footfalls or movements of the center of mass over a stride.

## Defining Gaits: Duty Factor and Limb Phase

The “gait” of four-legged land vertebrates (known as tetrapods) involves a precise sequence and coordination of the limbs as forward movement takes place. It is the sequence and timing of the limb contacts that essentially define different gait types. As tetrapods move forward, each limb

touches the ground, moves backward, is lifted off the ground, and brought forward again. This pattern results in a contact phase (called the support or stance phase) and a noncontact phase (called the swing phase), which together represent a locomotor cycle or *stride*. A few animals like birds, fast-moving reptiles, some nonhuman primates, and humans most obviously adopt a bipedal gait in which the entire weight of the body is supported solely by the hind limbs with right- and left-foot contacts alternating evenly during the stride (see “► [Bipedalism](#)” entry).

There is an obvious relationship between speed and the proportion of the stride for which the limbs are on the ground (the technical term for this is known as *duty factor*). At higher duty factors, when the limbs spend more than 50% of the stride on the ground, an animal is walking; at lower duty factors, when the limbs spend less than 50% of the stride on the ground (and are all off the ground at some point during the stride), an animal is running. This is easiest to observe in a biped like yourself. During walking, right and left footfalls alternate with at least one foot remaining on the ground at all times. During running, in contrast, both feet are off the ground at some point during the stride, and an aerial phase is introduced.

Walks and runs are examples of what are known as *symmetrical* gaits (Howell 1944; Hildebrand 1985; Cartmill et al. 2002, 2007). Gaits are considered to be symmetrical when pairs of limbs (front or back pairs) touch the ground at even time intervals (Fig. 1a). In other

**Gait, Fig. 1** Symmetrical and asymmetrical gaits in the horse. During a symmetrical step (**a**), left and right hind limbs (RH and LH) and forelimbs (RF and LF) contact the ground at even time intervals (horizontal bars in figure). In this particular symmetrical gait known as a running trot, there is a whole-body aerial phase (no bars), and the limb phase is nearly 50%, resulting in contralateral pairs of limbs (LH and RF; RH and LF) striking the ground almost simultaneously (see text for more details). During an asymmetrical step (**b**), pairs of hind limbs and forelimbs touch

the ground at irregular time intervals. In this particular asymmetrical gait known as the transverse gallop, the leading hind limb and forelimb (i.e., the limb of a fore and hind pair still in the air when the other limb of that pair strikes the ground) are on the same side (LH and LF are the leading limbs in this sequence). The whole-body aerial phase that follows touchdown of the forelimbs (last panel on the right) is not shown. (All images redrawn and adapted from Gambaryan (1974))

words, the time elapsed between the touchdowns of the right and left hind limbs should equal half of the stride total time. When pairs of limbs touch the ground at uneven time intervals, this results in *asymmetrical* gaits (Howell 1944; Hildebrand 1985; Fig. 1b). Put differently, symmetrical gaits are generally sequenced front to back. In symmetrical gaits like a walk, the contact of a hind limb is followed by that of a forelimb, or the contact of a hind limb/forelimb pair is effectively simultaneous as in the trot (Fig. 1a). Asymmetrical gaits are generally sequenced side to side. For such gaits, the contact of a hind limb is often simultaneous or immediately followed by that of the contralateral (opposite side) hind limb and then followed by a forelimb (Fig. 1b). Gaits such as the

bound, half bound, and gallop are all considered asymmetrical (Howell 1944; Gambaryan 1974; Hildebrand 1985). The bound, which is repetitive and appears symmetrical, is actually asymmetrical because two simultaneous hind limb contacts are followed by two simultaneous forelimb contacts. The half bound involves simultaneous contact of the hind limbs followed by sequential contact of the forelimbs. The most characteristic and best-known asymmetrical gait, the gallop, involves sequential contact of the hind limbs followed by that of the forelimbs (Fig. 1b). During the gallop, the limb of a pair of hind limbs or forelimbs that lands first is known as the trailing limb, while the other limb still in the air is defined as the leading limb. When leading hind limb and forelimb are

ipsilateral (same side), a transverse gallop results; contralateral leading hind limb and forelimb are found in a rotatory gallop (Howell 1944; Hildebrand 1985). All these asymmetrical gaits are characterized by an aerial phase (also known as suspension), either between hind limb and forelimb contacts or at the end of the stride. Interestingly, the canter, an asymmetrical gait equivalent to a slow gallop, has sometimes no aerial phase (Howell 1944; Schmitt et al. 2006).

Thus, it is clear that the sequence at which the limbs strike the ground or footfall sequence during a stride (referred to as the *gait cycle* [Cartmill et al. 2002, 2007]) defines specific gait types. A footfall sequence can be expressed as a percentage by calculating the time taken between the fore footfall and hind footfall on the same side during a stride (Hildebrand 1985; Cartmill et al. 2002, 2007). The technical term of this measure of interlimb coordination during forward movement is known as the *limb phase*. Terms such as “diagonality” and “gait number” have also been used and are essentially treated as synonymous.

Limb phases are known to vary quite a bit between quadrupedal animals and even within a single species (e.g., different horse breeds). This variation results in a broad spectrum of interesting gaits. Here are a few examples. At limb phases approaching 0% or 100%, the fore- and hind limbs on the ipsilateral side of a quadrupedal animal strike the ground pretty much at the same time. This is known as a *pace*. At limb phases closer to 50%, the fore- and hind limbs on contralateral sides of the same quadrupedal animal strike the ground almost simultaneously. This is known as a *trot*. As limb phases deviate from that 50% mark, either lower or higher, the limbs strike the ground in a specific order known as *lateral sequence* or *diagonal sequence* (Hildebrand 1985; Cartmill et al. 2002, 2007). In a lateral-sequence gait, the footfall of a forelimb (F) follows that of the hind limb (H) on the ipsilateral side (RH, RF, LH, LF); in a diagonal-sequence gait, the footfall of a forelimb (F) follows that of the hind limb (H) on the contralateral side (RH, LF, LH, RF) (Hildebrand 1985; Cartmill et al. 2002, 2007; Fig. 2). As the limb sequence proceeds with forward movement,

**Gait, Fig. 2** Sequence of footfalls for lateral-sequence and diagonal-sequence gaits. In a lateral-sequence gait (a), the footfall of a forelimb (F) follows that of the hind limb (H) on the ipsilateral side, which results in the following sequence: RH, RF, LH, LF. In a diagonal-sequence gait (b), the footfall of a forelimb (F) follows that of the hind limb (H) on the contralateral side, which results in the following sequence: RH, LF, LH, RF

some limbs are on the ground (in stance phase); others are off the ground (in swing phase). Unless the speed is really slow, only two limbs provide body support at some point of the walking stride. When contralateral limbs provide body support (e.g., RH and LF), this is known as a diagonal bipod; when ipsilateral limbs provide that support (e.g., RH and RF), it results in a unilateral bipod (Cartmill et al. 2002, 2007). Diagonal bipods are inherently more stable than unilateral bipods, and most animals seem to optimize periods of diagonal bipedality over unilateral bipedality (see Cartmill et al. (2002, 2007) for in-depth modeling and theory).

When walking, most tetrapods including most mammals adopt a lateral-sequence footfall sequence with diagonal couplets (i.e., a pair of contralateral forelimb and hind limb swings forward, while the other contralateral pair supports the body; Fig. 3a) or LSDS gaits (Hildebrand 1985; Cartmill et al. 2002, 2007). Such limb sequence is thought to result in greater stability during walking (i.e., forward motion without falling or stumbling) as a wider base supports the

**Gait, Fig. 3** Couplets used during different gaits. When a pair of limbs on the opposite side (contralateral) swings forward while the other contralateral pair on the other side supports the body, this is known as a diagonal couplet shown by the horse (a). When a pair of limbs on the

same side (ipsilateral) swings forward while the other ipsilateral pair supports the body, this is known as a lateral couplet shown by the camel (b). (All images redrawn and adapted from Gambaryan (1974))

body center of mass when three limbs are on the ground (Hildebrand 1985; Cartmill et al. 2002, 2007; see following section on movements of the center of mass during locomotion). There are exceptions in the mammal world, however. For example, some long-legged mammals (e.g., camels) or certain horse and dog breeds prefer lateral-sequence footfall sequence with lateral couplets (i.e., a pair of ipsilateral forelimb and hind limb swings forward, while the other ipsilateral pair supports the body; Fig. 3b) or LSLC gaits commonly known as pacing (Hildebrand 1985; Cartmill et al. 2002, 2007). Another important exception is the adoption by virtually all nonhuman primates of a diagonal-sequence footfall sequence with diagonal couplets or DSDC gaits during quadrupedal walking (Hildebrand 1967; Vilensky and Larson 1989; Cartmill et al. 2002, 2007). Outside of nonhuman primates, DSDC gaits are also common in the woolly opossum (genus *Caluromys*) and the kinkajou (genus *Potos*) (Hildebrand 1985; Cartmill et al. 2002, 2007; Lemelin et al. 2003; Lemelin and Cartmill 2010), which like nonhuman primates move and forage in the trees, particularly where thin and pliable branches abound. This complex fine-branch environment is believed to have played an important role in the evolution of diagonal-sequence gaits (Cartmill et al. 2002, 2007; Lemelin et al. 2003; Lemelin and Cartmill 2010).

Nonhuman primates are also unusual in the way they run. A typical run in a quadruped involves a whole-body aerial phase for which all limbs are off the ground at some point during the stride (think of a running trot in a horse). Primates almost never trot, and some species prefer the canter instead of galloping (Schmitt et al. 2006). In lieu of trotting, primates rely on the *amble*, a symmetrical running gait characterized by only pairs of limbs (forelimbs or hind limbs) undergoing an aerial phase (identified by Muybridge 1887 and Howell 1944 and later described in detail by Schmitt et al. 2006). In other words, there is no whole-body aerial phase as at least one limb contacts the substrate at any time of the ambling stride. Elephants rely on a similar running strategy, although their ambles have a lateral sequence compared to the diagonal sequence of nonhuman primates (Gambaryan 1974; Schmitt et al. 2006; Fig. 4). Despite adopting the amble, the functional reasons why nonhuman primates and elephants rely on such running gaits are quite different. Nonhuman primates maximize contact with an unstable branch (a very good thing to avoid a fall), while elephants maximize contact with the ground and avoid a whole-body aerial phase, possibly in order to moderate stresses on their limbs (a very good thing to avoid a bone fracture). Since the body never undergoes a complete aerial phase during an amble compared to a trot, the vertical

**Gait, Fig. 4** Ambling gaits in the Asian elephant (a) and baboon (b). A forelimb (F) or hind limb (H) remains in contact with the ground at all times during the step. Note

the lateral sequence in the elephant (RH, RF) compared to the diagonal sequence in the baboon (RH, LF). (All images redrawn and adapted from Gambaryan (1974))

oscillations of the body center of mass (and resulting force) are also less pronounced, which is again advantageous for moving on an unstable, pliable branch or mitigating limb stresses (Schmitt et al. 2006).

### Defining Gaits: Movements of the Center of Mass

Defining gaits visually is effective and relatively straightforward; it tells us a lot about what animals are doing. Another way to define gaits is by the movements of the animal's center of mass (COM). During walking and running, the movements (acceleration and deceleration) of the COM follow different patterns, and the vertical movements can differ between gaits (see Cavagna et al. 1977). When an animal walks, it tends to maintain relatively stiff limbs (limited joint flexion and limb compression), and because of the angles of the arc the leg sweeps, the COM of the body will rise and fall like an upside-down pendulum. At its highest point (which corresponds to mid-support of the contact phase when the hand or foot is directly below the shoulder or hip), this inverted pendulum has the greatest amount of gravitational

potential energy. As the COM falls, that energy is converted into kinetic energy and is used to drive the COM downward and forward. Using the limb as a relatively stiff pivot, it will “push” the COM back up, restoring potential energy to be used again in the next stride. During running, animals often allow their limbs to flex more deeply, and the COM is at its lowest point at mid-support. In doing so, the COM behaves more like a bouncing ball than a pendulum, stretching muscles and tendons and storing energy in them. Recent research has suggested that discontinuity in the path of the COM (i.e., the redirection of the COM from downward to upward or so-called collisions) is a more important variable to consider and represents an alternative way to envision locomotion that unifies all gaits under a single model (see Bertram 2016 for a thorough review). The costs of different gaits are thought to relate to the level of energy exchange or the cost of redirecting the COM, and that specific footfall sequences are chosen to minimize the latter (see Griffin et al. 2004). The question of why animals shift gaits as a result of changes in energetic costs, loads, or other factors remains an active area of research and discussion, but far beyond the limits of this entry. Suffice it to say that gait choice

appears to be profoundly complex and context specific.

## Conclusions

As animals move, they adopt specific gaits or sequences of footfall contacts with the substrate. A wide variety of gaits exist and are used by tetrapods. Gaits can be defined visually based on (1) the sequence of footfalls and the presence or absence of an aerial phase or (2) by movements of the center of mass during a stride. Gaits can be further subdivided into patterns with sequenced limb contacts (such as the walk, amble, canter, or gallop) or simultaneous limb contacts (such as the pace, trot, or bound). Regardless of the way gaits are defined, they represent the fundamental unit of motion for legged animals. The gaits that animals select represent their mechanical needs in specific situations and reflect both selective and situational priorities.

## Synonyms

Chicken-like bird locomotion; Land fowl gait

## Definition

Movement used by the members of the Galliformes order (chicken, quail, partridges, pheasants, turkeys, peafowl, grouse, quail, and guineaowl) to traverse their environment.

Galliformes is an order of terrestrial birds divided into three families, Phasianidae or Old World Quail (chicken, quail, partridges, pheasants, turkeys, peafowl, and grouse), Odontophoridae (New World Quail), and Numididae (Guineaowl). Until recently, two other families, Cracidae (Chachalacas and Curassows) and Megapodiidae (Malleefowl and brush turkeys), were also included under the order of Galliformes; however, they have now been placed in a separate order known as the Craciformes (Coles 2009). This chapter will discuss only the species included under the three families of Galliformes. There are approximately 290 species found worldwide on every continent, except Antarctica. Gallinaceous birds inhabit a variety of habitats including forests, farmlands, grasslands, woodlands, mountains, meadows, savannas, riverbanks, sand dunes, deserts, and city parks (Crespo et al. 2018; Coles 2009). These birds are important to humans as several species, including chickens and turkeys, have been domesticated for meat and eggs. Humans also hunt game birds, such as wild turkeys, quail, partridges, and pheasants, for sport (Howard 2004).

Galliformes vary in size ranging from the small king quail, which weighs 28–40 g to the large North American wild turkey weighing up to 14 kg (Crespo et al. 2018). Most are medium sized birds that have similar body forms and behavioral characteristics to domestic chickens. These birds generally have short rounded wings, short bills, large stout legs and feet, three forward pointing digits, and a fourth digit directed caudomedially (Coles 2009). Some species, such as the wattles and casques, have elaborate head and neck ornamentation. Their plumage coloration can be cryptic to dark to brightly colorful depending on the species and gender (Howard 2004). Galliformes are mostly granivorous to slightly omnivorous. They feed on the ground and search for seeds, fruits, nuts, roots, and invertebrates with their feet (Coles 2009; Crespo et al. 2018).

While these birds have wings, most are incapable of long, sustained flights, and are able to fly only short distances. Thus, Galliformes are considered resident birds and a majority are non-migratory. There are a few species known to be

capable of making extensive flights and migrating such as grouse and guineafowls. Altitudinal migration is also common in species living in high altitudes, such as the Ptarmigan (*Lagopus mertus*), Willow grouse (*Lagopus lagopus*), crimson horned pheasant (*Tragopan satyra*), and Eurasian quail (*Coturnix japonica*), as they must fly to reach their foraging areas (Coles 2009).

## Terrestrial Locomotion

Domestication of chickens, turkeys, and quail has made these gallinaceous birds more accessible for studying their locomotion. Therefore, most of this chapter's discussion will focus on these species. Birds in general, "inherited bipedalism and many hindlimb morphological features from theropod dinosaurs, an ancient lineage that first appeared around 230 million years ago" (Daley 2018, p. 884). During terrestrial locomotion, Galliformes use alternating hindlimbs to support their body (Gatesy 1999). In bipedal walking and running, the feet alternate half a cycle out of phase with each other. Such gaits are generally classified as walking if the duty factor (the fraction of the time for which each foot is on the ground) is greater than 0.5 and running if it is less than 0.5 (Alexander 2004).

When walking, the hindlimb movements of chicks can be broken down into two phases, swing and stance, which together create one stride. Swing phase is the period when the foot is lifted above the ground, and the stance phase is the period when the foot is in contact with the ground. The swing phase begins with swing flexion as the hips, knees, and ankle joints are flexed and the foot is lifted off the ground. The three muscles that are mainly responsible for swing flexion are the *m. sartorius* (hip flexor and knee extensor), *m. iliofibularis* (hip extensor and knee flexor), and *m. tibialis anterior* (ankle dorsiflexor). Then during swing extension, the knee extends by use of the *m. femorotibialis*, while the hips and ankles are kept in flexion, bringing the foot forward with respect to the body. At the end of the swing phase, the lateral and medial *m. gastrocnemius* plantarflex the ankle, and the foot is placed on the ground, initiating stance

phase. During stance phase, the knee and ankle flex, while the hips extend slightly. The amount of flexion on the ankle is minimal and is maintained at a relatively constant joint angle for most of stance phase. Stance phase involves continuous activity of many hindlimb muscles, including lateral and medial *m. gastrocnemius*, *m. iliotibialis posterior* (hip and knee extensor), *m. ilirotrochantericus posterior* (medial rotator of thigh), and *m. ischiofemoralis* (lateral rotator of thigh). Towards the end of stance phase, when the chick's trunk has moved ahead of the point of contact with the ground, the ankle extends. This backward movement of the limb with respect to the body aids in supporting and propelling the chick forward (Jacobson and Hollyday 1982). When the foot is planted on the ground during the stance phase, the ground produces an equal and opposite reaction force that passes through the center of mass (COM). This balance of forces supports the body and helps with either deceleration or propulsion (Morrison et al. 2018).

An inverted pendulum model is used to describe the energy mechanics involved in walking. Walking is considered to be energetically efficient because of the exchange between potential energy (PE) and kinetic energy (KE). In the middle of the stance phase, the leg acts as a solid strut, allowing for the body's COM to reach its maximum height. Here, PE is maximized, while KE is minimized. As the body moves in front of the leg, the COM falls converting PE into KE as PE decreases and KE increases. When both limbs are equally weight bearing, the COM is at its lowest and the forward velocity is at its highest, thus PE is minimized and KE is maximized. As the opposite leg begins its stance phase, bringing the COM upwards, the KE is then converted back in PE (Muir et al. 1996).

Due to their long and powerful hindlimbs, Galliformes are excellent runners (Morrison et al. 2018). As they increase their speed, these birds transition from a walking gait, to a grounded running (without an aerial phase), to a running gait (with an aerial phase) (Granatosky et al. 2018). Just like walking, running consists of a stance phase and a swing phase, forming one stride (Gatesy 1999). To move faster, birds

increase their stride length and stride frequency. Stride length is increased by further extending the hip, knee, and ankle at the end of stance phase. To increase stride frequency, stance duration is decreased by reducing the amount of time that the foot is in contact with the ground, thus leading to an aerial phase. As speed increases, there is greater muscle shortening rather than greater muscle force, causing an increase in joint movements (Morrison et al. 2018).

Changes in the movement of the hip and knee joints allow for changes in speed. When the feet contact the ground (touchdown), the hip flexes slightly followed by a period of hip extension throughout the stance phase. To draw the leg up and forward in the swing phase, the hip is flexed again before re-extending for touchdown. At low speeds, the hip joints remain relatively stable. At higher speeds, the arc of stance phase hip extension increases to over 40 degrees at 3.0 m/sec. At the fastest running speeds, the hip angle peaks at approximately 90 degrees. After toe contact, the knee joint flexes and the limb compresses, drawing the foot backwards. At low speeds, the knee continues to flex throughout ground contact. As speed increases, the knee extends later into the stance phase, and at the beginning of the swing phase, it flexes more rapidly to bring the foot off the ground. During the swing phase, the knee extends, projecting the foot forward for the following step. At all speeds, the arc of knee flexion during stance phase is relatively large averaging between 45 and 65 degrees. Pelvic rotations are relatively small but gradually pitch forward with speed. Overall, movement at higher speeds is initiated by knee flexion and then amplified by hip and knee extensions later in the stance phase (Gatesy 1999).

In contrast to walking, PE and KE simultaneously increase and decrease during running, making this exchange impossible. Instead, running is a spring-like gait that involves exchanges between elastic energy and KE (Muir et al. 1996). The leg serves as a spring during running. In the beginning of the stance phase, the leg is compressed, absorbing KE and storing it as elastic energy in the leg muscles and tendons (Muir

et al. 1996). In the latter half of stance, the tendons recoil and the elastic energy is released as KE, propelling the body upward and forward. This stretch and recoil of the tendons helps conserve energy while running (Morrison et al. 2018). The body's COM is lowest at mid-stance and highest during suspension, when forward velocity is also the greatest (Muir et al. 1996).

## Aerial Locomotion

The majority of Galliformes, such as pheasants, partridges, grouse, and turkeys, fly only short distances and cannot disperse far from their environment. This is due to these species being short-winged, heavy-bodied, and ground dwelling (Fig. 1). The *Cortunix* quail is an exception. As a result of their small body size and high aspect-ratio wings, these birds can disperse far and travel long distances. Among the partridge genera, the *Margaroperdix* of Madagascar and *Anurophasis* of alpine New Guinea can also travel long distances; however, their body type is similar to that of short-distance fliers (Hosner et al. 2017).

In Galliformes, a certain type of flight known as fast flapping with tip reversal is employed. In small birds, fast flapping is used during takeoff and landing, but in larger birds, it is seen just prior to landing. There are two phases involved in flapping: downstroke and upstroke. During downstroke, the wing starts off fully extended followed by rotation of the wings around the shoulder joint. When this occurs, the wing tips are horizontal, and the downstroke finishes off with the wings forming in front of the body. The second part of the cycle involves the upstroke, which begins with the wings extended ventrally. After this, the humerus is flexed and rotated. Then, the wing tips separate, and the wings start to extend and produce a rapid, propulsive flick (Brown 1963). An important part of developing flight is this "wing-stroke," which is employed by ground birds shortly after hatching. Although hatchlings have yet to form functional wings, the wing-stroke is important because it allows birds to navigate habitats and eventually helps them fly (Dial et al. 2008).

**Galliformes Locomotion, Fig. 1** Wing morphology (a) and skeletal morphology (b) in different age classes of the Chukar partridge (*Alectoris chukars*). Figure adapted from Tobalske et al. (2017) with permission

Field observation reveals that the ability to fly decreases with increasing body size in birds. One explanation for this is that the maximum power formed by the flight muscles could be limited by wingbeat frequency, which depends on mass. Another contribution for shorter flight time in these birds is the low-myoglobin content and glycolytic fibers found in the pectoral muscles, which provides bursts of energy for short-distance flight. In comparison, birds such as doves contain oxidative muscle fibers, allowing for longer flight times. Other factors that can affect how much power is available for flight are the proportion of time spent shortening and timing muscle activation and deactivation (Tobalske and Dial 2000).

Many birds in the Phasianidae family, the largest family in the branch of Galliformes, utilize rapid takeoff. These birds include northern bobtail (*Colinus virginianus*), chukar partridge (*Alectoris chukar*), ring-necked pheasants, and turkeys. These species use a similar wingbeat during take-off, which is a vortex-ring gait with tip reversal. The backward flick at the end of a tip reversal increases lift production during the downstroke. For ground dwelling birds with rounded wings, using tip reversal is unusual, but it could provide rapid acceleration during takeoff (Tobalske and Dial 2000).

The vertical acceleration needed for rapid take-off is achieved by jumping and is critical for many ground-dwelling birds such as phasianids. Jumping is an integral part of flight because it helps birds escape from predators and helps initiate flight. The musculature in the legs of these birds are adapted for walking and running as ground-dwelling birds, but also must be able to provide high power outputs to jump into the air. This is due to the energy requirements after take-off to maintain an upward trajectory after leaping into the air. Immediately after takeoff, the flight muscles in these birds produce large amounts of power to continue climbing (Henry 2005).

Prior to flying, birds must first develop wing-flapping. Wing-flapping is essential in both flying and walking. It can occur without flight and can be seen in young birds that have not developed wings. For example, in White Leghorn chickens, Red Jungle fowl, Japanese quail and Cornish Rock Chickens, wing-flapping is evident immediately after hatching (Provine et al. 1984). Wing-flapping can occur without flight. Flight-flapping requires a significant amount of mechanical power that occurs due to the contraction of the pectoral muscles (Jackson et al. 2011).

Other than flying, Galliformes also utilize wing-assisted incline running (WAIR), which is

**Galliformes Locomotion,**

**Fig. 2** Locomotor development of Chukar partridge (*Alectoris chukars*) from hatching to adulthood. Fledglings begin using their wings 5 days post hatch to ascend inclines in wing-assisted incline running (WAIR) and to slow their fall from elevation. “Stroke curves represent the trajectory of the wing. Vectors indicate average lift during WAIR and estimated lift during slow level flight and descent.” Figure adapted from Tobalske et al. (2017) with permission

a behavior that consists of flapping wings and running with legs to climb sloped structures like trees, cliffs, etc. It is typically used as a form of escape from predators by ground dwelling Galliform birds. For example, chukar partridge can run up on vertical inclines when utilizing WAIR. Also, chukar hatchlings as young as three days old can use their partially formed wings to ascend (Fig. 2). When utilizing WAIR, birds experience different vectors of acceleration during downstroke. During the first part of the downstroke, the acceleration of the bird's COM is oriented in the direction of travel. In the later stages, the COM receives an acceleration towards the substrate. These aerodynamic forces produced by their wings aid their legs in climbing up higher and steeper terrain. In precocial hatchlings, these birds utilize their underdeveloped wings to move up small inclines (Bundle and Dial 2003). As they grow older and engage in more WAIR, the aerodynamic forces from the wings also increase due to the maturation of feathers, skeletal structures, neuromuscular control, and muscle contractile properties (Tobalske et al. 2017).

There are a variety of different directions birds can take during WAIR; however, the basic wing path remains the same. Specifically, in the wing joints, the glenohumeral joint controls most wing movements. The acrocoracohumeral ligament (AHL) goes across the glenoid from the acrocoracoid process to the transverse sulcus of the humerus. The AHL restricts humeral pronation and controls the pitch of the body in between the wings. It also stabilizes the glenohumeral joint to prevent dislocations. During WAIR, the humeral head rolls in a complex pattern but is restricted to the dorsal side of the joint surface. In addition, the distal joints are responsible for changing the wing shape (Baier et al. 2013).

Wing-assisted incline running only requires a fraction of the muscular effort compared to level flight. As such, chukar partridges and other ground-dwelling birds preferentially use WAIR compared to other forms of flight when placed on an inclined obstacle. There is also minimal neural activity when using WAIR and only recruitment of a few regions of the pectoral

muscles. By also recruiting the hindlimbs and forelimbs during WAIR, it reduces the strain on the pectoral muscles and allows energy to be conserved for more energy consuming flight (Jackson et al. 2011).

## Impact of Domestication

Domestication of Galliformes, such as chickens and turkeys, has a significant impact on their gait. The broiler chicken (*Gallus gallus domesticus*) is a major part of the human food supply. These chickens have been selectively bred for hundreds of years for increased size and growth rate (Paxton et al. 2013). High growth rates, stocking density, diseases, nutritional deficiencies, air quality, light, age, and genetics are factors associated with lameness in broiler chickens (Granquist et al. 2019). Birds with leg weaknesses are prematurely culled or have an increased incidence of mortality, which then affects the farm's profitability. The most common leg pathologies seen in broiler chickens include bacterial chondronecrosis with osteomyelitis and rotational and angular deformities. These pathologies are observed at high incidences in chickens at all developmental stages, which highlights the problem of maintaining high growth rates and muscle masses (Paxton et al. 2014).

Compared to their wild counterparts, broiler chickens have a much larger body mass. This increase in mass places greater stress on their hindlimb muscles during standing and movement. Therefore, to support their bodies, these chickens must increase their hindlimb muscle mass especially in their hip and knee extensors. Larger feet are also necessary to help improve their stability during the stance phase. However, larger feet affect the broiler chicken's ability to accelerate and decelerate the limb during swing phase. As the birds continue to grow, more metabolic energy is required to accelerate and decelerate. This energy cost may be a factor contributing to the reduced activity levels seen in broiler chickens.

Although domestic chickens rely more on hindlimb muscles for terrestrial locomotion, their breast muscles have also increased in response to artificial selection for meat production. Breast

muscle mass increases faster than body mass. However, there is no significant change in wing mass, which is consistent with decreased flight frequency and ability observed in broiler chickens (Tickle et al. 2014). The growth of pectoral muscles is observed between 4 and 6 weeks of age and this increase in muscle mass causes a shift in the COM position from a caudodorsal to a craniodorsal position. This shift in COM then requires an increase in muscular force to balance it out. Increase pectoral mass also compromises the efficacy of the chicken's respiratory apparatus (Paxton et al. 2014).

As a result of selective breeding, in comparison to other Galliformes, broiler chickens move slower and more carefully to compensate for their large sizes (Paxton et al. 2013). Changes in limb orientation are observed in these chickens. When standing, their limbs are more flexed and when walking, their limbs are more extended (Paxton et al. 2014). When walking, these birds place their feet at a more lateral position, providing an increased potential for medial lateral motions around the COM. While one limb is in swing phase, the body is moved laterally over the contralateral limb in stance phase. For stability, they fine tune their step length and width to control their COM. These exaggerated medial and lateral motions suggest broiler chickens may share more in common biomechanically with waddling birds such as penguins, geese, or ducks, than the wild Galliformes (Paxton et al. 2013).

Similarly, domesticated turkeys have been bred to be larger than their wild counterparts. Without proper limb compensation for their increased body mass, the COM is altered and the stance is wider, leading to changes in gait. Unlike wild turkeys, domesticated turkeys walk with emphasis in the mediolateral forces, similar to a waddling gait. These birds may also have a long stance duration with high frequency strides, leading to a shuffling gait. This shuffling gait increases stability but reduces the speed. Furthermore, as turkeys are bred for meat production, especially the breasts, these large pectoral muscles can interfere with their legs while walking (Stover et al. 2018).

## Influence in Understanding Human Locomotion

Although there are numerous differences between humans and birds, the principle similarity is that both are strictly bipedal (Müller et al. 2016). As a result, ground dwelling birds can serve as animal models when studying the integration of mechanics and neuromuscular control for bipedal locomotion (Daley 2019). Digitigrade posture in birds versus plantigrade posture in humans is a significant difference affecting locomotor mechanics. Birds have digitigrade posture due to their near horizontal femurs and elongated tarsometatarsal (proximal foot bones in humans) segments. Humans are plantigrade and have a vertically oriented femur during quiet standing (Müller et al. 2016). However, this difference does not exist in the early locomotor development of children. Children initially learn to walk in a digitigrade pattern and gradually transform to an adult-like plantigrade pattern after 1–2 years. Many of the changes seen during locomotor development in humans are also observed in chicks but over a shorter period. Both chicks and children must eventually be able to stabilize and support their bodies on one leg to develop a bipedal gait. This developmental change to a single leg support as well as changes in duty factor occurs in humans around 6–7 years of age (Muir et al. 1996). Comparing the development of bipedal locomotion between ground dwelling birds like Galliformes and humans can further our understanding of human locomotor development.

Bipedal animals avoid falls, collisions, and injuries, when moving across varied terrain through precise control of limb substrate interactions (Daley 2019). The adaptations used by birds and humans when running on uneven terrain are quite similar. The conservative spring mass model is used to describe both human and bird running. When adjusting to drops or downward steps, the leg angle at touchdown and the initial leg length are increased. When adjusting to obstacles and upward steps, the leg angle at touchdown and the initial leg length are decreased. Due to morphology, birds have a greater range of leg angle

and leg length adaptations than the restrictive straight leg of humans. The major difference between humans and birds is the leg angle at touchdown. On level ground, the leg angle in birds is usually between 40 and 68°, while in humans it is steeper at around 60–80° (Müller et al. 2016). The human leg instead is better adapted for leg stiffness changes when running on uneven ground. While birds lengthen their legs to cope with level discrepancies, humans not only adjust the leg angle and leg length but can also reduce their leg stiffness. If humans needed to increase their range of leg lengthening, they would move in a less upright posture. It has been theorized that early humans walked bipedally in a crouched position with more flexed hips and knees, similar to birds (Müller et al. 2016). This understanding of how ground-dwelling birds traverse terrain can be applied to designing and controlling bioinspired robotics and human-assisted devices.

## Conclusion

As a result of the domestication of chickens and turkeys, the locomotion of the Galliformes is exceptionally well-studied. Galliformes are predominantly ground dwelling birds that move by foot because it is energetically favorable. In bipedalism, the inverted pendulum model and the conservative spring model are used to describe the energy mechanics involved in walking and running, respectively. Only a few species of Galliformes fly long distances. Most of the other species fly short distances due to their large body size and low myoglobin containing glycolytic muscle fiber type. Fast flapping, rapid take off, jumping, and WAIR are used for traveling, avoiding predators, and searching for food. By domesticating some of these birds for meat and eggs, humans have altered their gait in comparison to their wild counterparts. As the evolution of bipedalism is shared among humans and Galliformes, studying locomotor behavior in these species can provide insight on the development of bioinspired robotics for clinical application.

## Gambling Fallacies

Thomas R. Zentall

University of Kentucky, Lexington, KY, USA

## Definitions

**The Monte Carlo or Gambler's fallacy** – The erroneous belief that if, in the recent past, a particular event occurs more frequently than expected, and it is less likely to happen in the future because probabilities should even out.

**The near miss fallacy** – A near miss (or more accurately near hit) is a special kind of failure to reach a goal, one that fails but comes close to being successful.

**Chasing losses, entrapment, or sunk cost** – Trying to win back money one has already lost, by gambling more.

## Introduction

Gambling fallacies are thought to result from the misunderstanding of probabilities: what it means for a series of events to be random and from the mistaken understanding of the effects of past events on future events (fairness and equity). As such, they may be unique to humans and probably do not apply to other animals. That is, they may be culturally determined. In other cases, however, animals like pigeons show evidence of having similar biases, and those are likely to result from basic behavior processes.

## The Monte Carlo or Gambler's Fallacy

Certain fallacies, like the *Monte Carlo fallacy*, are unique to humans because they are based on what we believe to be characteristic of the fair distribution of random events. If one flips a coin four times and each time it comes up heads, many people would believe that the probability that it will come up heads again is much less than 50%, to make up for the unlikely outcome of four heads in succession. But coin tosses are

independent – the coin has no memory of its past behavior. As most animals live in an unpredictable world, one in which purely random events would be very rare, animals become sensitive to short-term changes in the probability of events. Thus, if animals are exposed to random events in which a particular event occurred four times in succession (e.g., left and right turns in a maze), they would be more likely to show a greater tendency to make that same response again. That is, because they live in a world in which the probability of events typically changes over time, they likely learn that the repeated event is now more likely to occur. Thus, if an animal were exposed to the coin flipping example, it would likely to act as if the coin was biased.

This phenomenon is related to *probability matching* in which humans are presented with two alternatives, but the probability of one being correct is greater than the other (e.g., 70% vs. 30%). Humans suboptimally tend to match those probabilities, responding 30% of the time to the lower probability event (Humphreys 1939). However, rats (Bitterman et al. 1958) and monkeys (Wilson and Rollin 1959) tend to choose the higher probability event, exclusively, thereby maximizing reinforcement. In both cases, humans attempt to do better than the experienced probability of the random events, whereas most animals do not.

## The Near Miss Fallacy

The *near miss fallacy* (more accurately referred to as the *near hit fallacy*) can most easily be seen in the way that slot machines function. Historically, slot machines have three reels, and the player wins when the pictures on the three reels match. The near hit outcome occurs when the first two reels match but the third does not. Curiously, when the probability of a win is equal, people prefer to play a slot machine with a higher rate of near hit outcomes (MacLin et al. 2007). Reid (1986) suggested that a near hit appears to be more similar to a hit than the other forms of losing because it is the only loss that is not apparent when the second reel stops.

Unlike humans, however, when pigeons are trained on a task, equated for losses, in which they can choose between an alternative with *near hit* trials and another alternative with other patterns of losses, they tend to avoid the alternative with the *near hit* trials (Fortes et al. 2017; Stagner et al. 2015). Apparently, for pigeons the similarity of the near hit losses to trials representing a win actually devalues the effects of a win. That is, because those losses look more like wins than other losses, they generalize to win trials.

What accounts for the difference between pigeons and humans? Humans tend to have considerable experience with tasks in which losses similar to a near hit actually represent progress towards a goal. Consider trying to get a basketball into a hoop. Initially, one might miss the hoop entirely. With practice one might get closer to putting the ball into the hoop but still not get it in. That incremental improvement would be evidence that one is making progress. The *near hit* in basketball represents an improvement. In the slot machine task, in which there is no skill, however, the near hit does not represent progress. But to a human, who has had considerable experience with tasks involving skill, it may feel like an improvement. Unlike a coin flip, the *near hit* is more closely related to skill tasks because in the sequence of the three events, the signal of a loss is delayed.

## Chasing Losses, Entrapment, or Sunk Cost

When gamblers start to lose, there may be a tendency to keep gambling to recoup the money that they have lost. This behavior comes under the larger category of *sunk cost*. *Sunk costs* are expenses that cannot be retrieved and, thus, should not factor into future investment decisions. But people will often invest additional funds in a failing business to try to make up for those losses, a behavior that typically results in additional losses. Gamblers who are losing will often do the same.

Research with animals suggest that pigeons, too, show a *sunk cost effect* (Pattison et al. 2012). In that study, pigeons were trained to peck a green button 30 times for food. They

were also trained to peck a red button 10 times for food. The pigeons were then tested with a choice. After they had pecked the green button a variable number of times, the pigeons were given a choice to continue pecking the green button or to switch to the red button. Regardless of the number of times that they had pecked the green button (e.g., only 10 times), the pigeons almost always chose to stay with the green button (see also Magalhães and White 2014; Navarro and Fantino 2005).

The research with pigeons suggests that the *sunk cost effect* does not result from not wanting to “give up” or the potential social consequences of failure. Instead, it may result from a tendency to misperceive that the consequence of persistence is more predictable of reinforcement than the consequence of switching to an alternative behavior. This behavior may be predisposed because in nature, it is likely that giving up on the current search may involve increased uncertainty, greater travel time, and the potential danger associated with travel.

## Conclusion

Examining the similarities and differences in the way that humans and other animals approach probabilistic learning tasks can identify which fallacies can be attributable to cultural information about the task and which can be attributed to basic behavioral processes, perhaps attributable to evolution.

## Game Theory

► [Ultimatum Game](#)

## Gametes

Rachna Verma  
Department of Molecular and Human Genetics,  
Banaras Hindu University, Varanasi, India

## Synonyms

[Ovum](#); [Reproductive cell](#); [Spermatozoa](#)

## Definition

Gametes are sex cells of organisms, haploid in chromosome content that fuse with other haploid

cells during fertilization in sexually reproducing organisms.

## Purpose of Gamete Formation

Gametes or reproductive cells are always haploid in sexually reproducing organism in order to maintain the chromosomal number constant in the species after getting combined with the gamete from the other partner. The new organism has half the chromosomes from its mother and half from its father. Sexual reproduction also helps in the maintenance of genetic diversity of organisms because each organism has a different combination of genes than either of its parents. For example, in humans, a sperm cell gets fused with an egg cell, producing a zygote that has a unique set of genetic information and correct number of chromosomes.

## Types of Gametes

There are two types of gametes in humans, male and female gametes. The male gamete is called sperm and has chromosome structure XY. The female gamete is called the ovum and has chromosome structure XX.

## Spermatogenesis

Spermatogenesis is a process of formation of male gametes that occurs in the seminiferous epithelium of the adult testis. The process of spermatogenesis gets completed in four phases and includes (1) the proliferation and differentiation of spermatogonia, (2) meiotic divisions of spermatocytes, and (3) the transformation of haploid round spermatids arising from the second meiotic division into spermatozoa (spermiogenesis), which (4) are released into the lumen of the seminiferous tubules (spermiation). Spermatogonia are the diploid ( $2n$ ) stem cells of spermatogenesis and can be divided into type A and type B. Type A spermatogonia have an oval euchromatic nucleus in contrast to type B spermatogonia, which have a round heterochromatic nucleus (ref

1). It is the type B spermatogonia that get differentiated and enter the process of meiosis. Meiosis starts with DNA synthesis of type B spermatogonia which lose contact with the basal lamina (preleptotene). After completion of DNA synthesis, each chromosome consists of two chromatids (C). These cells are named primary spermatocytes, and the DNA content is tetraploid ( $2n;4C$ ). Primary spermatocytes undergo the first meiotic division that results into the formation of haploid secondary spermatocytes with diploid DNA content ( $1n2C$ ). Secondary spermatocytes undergo the second meiotic division after a short interphase of about 6 h in the human without DNA synthesis. By this division, chromatids are finally separated leading to round spermatids with a haploid number of chromosomes and DNA content ( $1n1C$ ). The transformation of conventional round cell spermatids into spermatozoa with the capacity for motility and fertilization of an egg includes a complex sequence of events: (1) formation of the acrosome, (2) condensation of the nucleus, (3) development of the sperm tail, (4) reorganization of cellular organelles such as mitochondria and centrioles, and (5) reduction of the cytoplasm. The length of the human spermatozoon measures about 60  $\mu\text{m}$ . The flat and oval head (diameter: 3  $\mu\text{m}$ , length: 5  $\mu\text{m}$ ) consists of the acrosome and the extremely condensed nucleus. The acrosome covers the head surface and contains numerous proteolytic enzymes, i.e., hyaluronidase, collagenase, neuraminidase, phospholipase A, acrosin, and others. The release of these enzymes, the so-called acrosome reaction, enables the spermatozoon to penetrate the "corona radiata" of follicle cells and the zona pellucida of the egg. Some nuclear vacuoles are common. The flagellum measures about 55  $\mu\text{m}$  in length. It possesses the central axoneme and is divided into neck piece, mid piece, principle piece, and end piece (Bergmann 2006; L'Hernault 2006; de Kretser et al. 1998).

## Oogenesis

Oogenesis occurs in the outermost layers of the ovaries. Oogenesis starts with a germ cell, called an oogonium (plural: oogonia). Oogonia undergo

mitosis to increase in number, eventually resulting in up to one to two million cells in the embryo. The cells that undergo meiosis are called primary oocytes. These cells will begin the first meiotic division but get arrested during the first prophase stage. At the time of birth, all future eggs are in the prophase stage. At adolescence, anterior pituitary hormones cause the development of a number of follicles in an ovary (Gilbert 2000). This results in the primary oocyte finishing the first meiotic division. The cell divides unequally, with most of the cellular material and organelles going to one cell, called a secondary oocyte, and only one set of chromosomes and a small amount of cytoplasm going to the other cell. This second cell is called a polar body and usually dies. A secondary meiotic arrest occurs, this time at the metaphase II stage. At ovulation, this secondary oocyte will be released and travel toward the uterus through the oviduct. If the secondary oocyte is fertilized, the cell continues through the meiosis II, completing meiosis, producing a second polar body and a fertilized egg containing all 46 chromosomes of a human being, half of them coming from the sperm (Bukovsky et al. 2005; Virant-Klun 2015). In some species, such as sea urchins and frogs, the female routinely produces hundreds or thousands of eggs at a time, whereas in other species, such as humans and most mammals, only a few eggs are produced during the lifetime of an individual. In those species that produce thousands of ova, the oogonia are self-renewing stem cells that endure for the lifetime of the organism. In those species that produce fewer eggs, the oogonia divide to form a limited number of egg precursor cells. In the human embryo, the thousand or so oogonia divide rapidly from the second to the seventh month of gestation to form roughly seven million germ cells. After the seventh month of embryonic development, however, the number of germ cells drops precipitously (Gilbert 2000).

## Conclusions

Gametogenesis is an essential process for the survival of the species. Any alteration in this process

leads to high-risk pregnancy cases. Any disturbance or alteration in the process of spermatogenesis like oligospermia, azoospermia, asthenozoospermia, and chromosomal anomalies leads to the higher percentage of male infertility. On the other hand, in the case of females, various conditions like polycystic ovarian syndrome and premature ovarian failure contribute to female infertility cases around the globe. Various research studies are in process throughout the world for solving these issues of infertility. There are many herbal products in markets for humans after their preliminary study on animal models.

## Synonyms

Encapsulated nerve-cell bodies

## Definition

An aggregation or assembly of neuronal cell bodies, usually in the peripheral nervous system (forming a nerve center) is termed a ganglion. The basic function of a ganglion is to serve as a connection between the central nervous system (CNS) and peripheral nervous system (PNS). *Plural-ganglia.*

## Introduction

The human nervous system consists of CNS and PNS. Located in the PNS, the cell bodies (which are known as ganglion) occur as a relay between them. The development of the human nervous system begins from the signals sent by the

notochord, which forms the structure called the neural tube, which later forms the neural crest.

There are two types of ganglia in the PNS. They are (1) sensory ganglia that are the cell bodies of sensory neurons and (2) autonomic ganglia, which are the cell bodies of efferent neurons from the autonomic nervous system.

## Evolution

The evolution of ganglia has taken place in their own pace during the evolution of different species. The simplest species in animal kingdom are under the phylum Porifera, e.g., sponges. These species do not have any nerve net organization or development of a brain. Apart from sponges, all other animals have a neural system or correlates to carry signals in their bodies. Nervous systems in hydra consist of sensory cells and ganglionic cells. Ganglions are thought to be formed from the neuroblast's migration in CNS (Blentic et al. 2011).

The most primitive nervous system is a diffuse nervous system found in Cnidaria and in Ctenophora (Encyclopaedia Britannica 2017). Here, a nerve net is formed beneath the epidermal layer of the organism. This diffused nerve net is found in flatworms (planaria), which also develop two cerebral ganglia at the cephalic end, forming part of a more complex central nervous system (Erulkar and Thomas 2020). The nervous systems of annelids, mollusks, and arthropods consist of nerve cords and ganglia running along the length of their bodies. Nematodes have a group of ganglia placed anteriorly consisting of nerve cells with a high degree of centralization. Nerve nets are absent here. Arthropods are diverse in nature and consist of three pairs of ganglia. The functions conducted by the ganglia of arthropods are vision control, control of tactile sensations and integration of sensory information (Erulkar and Thomas 2020). Few studies have shown clusters of ganglia in mollusks in relation with the enteric nervous system. Species such as crabs and snails consist of several ganglia. As the organizational level of organisms become more complex, the level of centralization and cephalization increases.

Gradually, the functions such as feeding and locomotion become specified in certain parts of the nervous system (Erulkar and Thomas 2020; Nicholls 1992).

In the vertebrates, the neurons gather in masses forming ganglionic structures in the peripheral nervous system. The cells associated with ganglion are called the ganglionic cells. On the other hand, in the invertebrates, there is no distinctive separation between the central nervous system and peripheral nervous system. The nerve nets and ganglionic bodies branch together as a diffused nervous system.

## Types of Ganglia

There are around 24 paravertebral ganglia in each chain in the human body. In the vertebrates, ganglia are classified into three major categories:

1. **Autonomic ganglia** consist of cell bodies of efferent neurons, associated with autonomic system. It has two sets of ganglia, the preganglionic neurons and postganglionic neurons.
2. **Cranial ganglia** consist of cranial nerve cell bodies.
3. **Dorsal root ganglia (spinal ganglia)** consist of afferent nerves cell bodies, associated with sensory neurons.

## Autonomic Ganglia

Autonomic ganglia are basically groups of neuronal cell bodies along with their dendrites. Autonomic ganglia consist of motor neurons and act as a connection carried by the autonomic nerves between the central nervous system and the target organs located at the periphery. Autonomic ganglia have two divisions of neurons that are antagonists to each other, i.e., the sympathetic ganglia and parasympathetic ganglia (Mai and Paxinos 2011). Both of these ganglia have sensory fibers associated with them. A set of myelinated neurons arising in the spinal cord or the brainstem are termed as preganglionic fibers, whereas the unmyelinated fibers located outside the central nervous system are the postganglionic neurons. The preganglionic neurons carrying relay information from the brainstem connect to the organs in the viscera through the postganglionic ganglia (Fig. 1). These ganglionic cells control visceral behavior, i.e., involuntary movements.

### (i) Sympathetic Ganglia

This is the ganglia associated with the sympathetic nervous system. The sympathetic ganglia are localized at distant region in front of the vertebrae from the target organ. The preganglionic sympathetic ganglia are present at the lateral horns of 12th thoracic till the second and third lumbar

**Ganglion, Fig. 1** Autonomic ganglia. Connections between the CNS and PNS occur through the ganglionic neurons. (a) Central nervous system, (b) peripheral

nervous system, and (c) effector organs: cardiac muscles, smooth muscles, or glands

**Ganglion, Fig. 2** Autonomic nervous system. Regulation and functioning of the organs carried by parasympathetic and sympathetic systems in human body. Spinal cord

segments represented as (1) T1–T12, thoracic segments; (2) L1–L2, lumbar segments; (3) S2–S4, sacral segments

region of the spinal cord. The sympathetic ganglia further have two types based on their location of cells (Fig. 2). There are 21–22 pairs of paravertebral sympathetic ganglia, present along the sides of vertebrae, and three prevertebral sympathetic ganglia (celiac, mesenteric and inferior mesenteric) located on the anterior side of aorta (Mai and Paxinos 2011). Sympathetic ganglia perform the function of carrying stress responses or danger signals.

### (ii) Parasympathetic Ganglia

The parasympathetic ganglia are associated with the PNS and present in the vicinity and adjacent to the organs it innervates. Preganglionic parasympathetic ganglia are localized at the brainstem and sacral region of the vertebral column (Fig. 3). On the other hand, the postganglionic parasympathetic ganglia are present near ear and urinary bladder. Parasympathetic ganglia are cholinergic in nature, i.e., secrete acetylcholine. Parasympathetic ganglia in association with the various cranial nerves (CN III, VII, IX, X)

have different functions such as salivation and secretory activities.

### (iii) Enteric Ganglia

The assembly of neurons enclosed within the wall of the gastrointestinal tract comprises of the enteric nervous system. This system controls motility along with the gastrointestinal tract and secretion.

### Cranial Ganglia

These are the sensory ganglia associated with the cranial nerves. They are located at the surface of hard and dense part of temporal bone. There are 12 pairs of cranial nerves in human beings. The trigeminal nerve is the largest nerve, and the trigeminal ganglion gives rise to three large nerves: ophthalmic, maxillary, and mandibular. The cell bodies of sensory fibers are predominantly present in this ganglion. The intermediate nerve of the facial nerve consists of parasympathetic fibers. Ciliary ganglion, submandibular ganglion, geniculate ganglion, and pterygopalatine ganglion are part of this nerve. Cranial nerve ganglia serve the function of controlling reflexes for head and neck.

**Ganglion, Fig. 3** Parasympathetic and sympathetic ganglia. Segmental divisions of brainstem and spine into three regions along with the fibers projecting from each segment have been represented

The sensory input carried by the fibers includes sensations like vision, taste, smell, hearing, and balance.

### Dorsal Root Ganglia (Sensory Ganglia)

The dorsal root ganglia (DRG), also termed as spinal ganglia, is normally located along the dorsal horn of the spinal nerve, i.e., close to intervertebral foramina. It contains cell bodies of primary afferent neurons, which are pseudo-unipolar neurons. Sensory ganglia are made up of unipolar neurons that are structures in oval shape which are located on DRG (Fig. 4). These cells undertake a T-shaped bifurcation allowing one branch to descend in periphery, while the other enters the spinal cord and brain (Mai and Paxinos 2011). Many cells, such as satellite cells, macrophages, lymphocytes, and endothelial cells, are found in the DRG. DRG carries the information (temperature, harm signals) to the central nervous system.

DRG consist of TRP channels and exhibit peripheral sensitization in the conditions of chronic pain. Therefore, recent studies are targeting DRG for treatment of neuropathic pain caused due to sudden and serious injuries (Berta

et al. 2017). The most common technique used is DRG radiofrequency ablation. The satellite glial cells (SGCs) found in the DRG form a tight envelope around the neuronal cells which generate response in conditions of nerve injury or inflammation (Haberberger et al. 2019). These contribute in neuropathic pain and participate in signal processing in sensory ganglia (Hanani 2005).

### Basal Ganglia

Basal ganglia (BG) are a set of nuclei, which is a part of gray matter in the cerebrum. Basal ganglia consist of certain structures: caudate nucleus, putamen, globus pallidus, nucleus accumbens, subthalamic nucleus and substantia nigra (Fig. 5) (Florio et al. 2018). Caudate nucleus and putamen (striatum) show excitatory activity in BG, whereas globus pallidus acts inhibitory (GABAergic neurons) sending signals to the thalamus. Dopamine plays an important role in stability of BG.

Specific regions of the striatum serve different purposes such expression and habit acquisition, which depend on the factors like DA inputs, cortical inputs and intrinsic circuitry (Florio et al. 2018). Basal ganglia are responsible for emotions

**Ganglion, Fig. 5** Basal ganglia. Position and parts of basal ganglia in the human brain. (a) Brain section representing location of basal ganglia, (b) structure of basal ganglia

and habit formation in humans. Along with this, it also contributes in decision-making, directional movement, and other cognitive processes.

### Conclusion

Ganglia are a set of nuclei, which either consist of afferent or efferent neurons outside the central

nervous system. These structures are located at various parts defining their particular functions in the organ. Primarily, ganglia serve as a relay for information transfer between the CNS and the PNS. Ganglionic structures have evolved along with the evolution of organisms. The sensory, autonomic, and cranial ganglia are present in the PNS, whereas an important ganglion termed basal ganglia is found only in CNS, specifically the

cerebrum. There are several studies and researches conducted on the sensory and cranial ganglia. The dorsal root ganglion and satellite ganglion cells are currently being subjected to study for treatments for neuropathic pain. Techniques such as DRG radiofrequency ablation and gene therapy are used in modern treatments (Hanani 2005).

## Synonyms

[Gause's exclusion law](#); [Gause's principle](#); [Grinnell's axiom](#); [The competitive displacement principle](#); [The competitive exclusion principle](#)

## Definition

Gause's law is a principle in the field of population dynamics first outlined by Russian/Soviet biologist G.F. Gause, which states that two species that are competing for the same limited resources cannot coexist at constant population values, that no two species with similar ecological niches can coexist in a state of stable equilibrium, or that realized ecological niches do not intersect. It is otherwise called the competitive exclusion principle (CEP). Three different basic outcomes have been specified: competitive exclusion, local extinction, and niche differentiation.

## Introduction

Population dynamics is a field that studies the change in the prevalence of different species over time in relation to four key life-path processes: birth, death, immigration, and emigration. Prior to Gause, after the initial nineteenth-century contribution of T.R. Malthus on the consequences of exponential population growth, the study of inter-species interaction in the early part of the twentieth century had been advanced through

important work by Alfred Lotka (1925) and Vito Volterra (1931 [1928]), which together yielded the Lotka-Volterra predator-prey set of differential equations, as Gause readily acknowledged (Gause 1932, p. 389). These equations modeled the association of two separate species or two groups within a species, one of which preys on the other with deadly intent as a result of asymmetric power relations. However, inter-species interactions are not limited to the very specific case of predator-prey relations, as the significant work of G.F. Gause would go on to illustrate.

### G.F. Gause

Georgii Frantsevich Gause – Георгий Францевич Га́йзе – (1910–1986) was a Russian/Soviet biologist born in Moscow who became a Professor at the Timiriasev Institute for Biological Research and the Zoological Museum in the University of Moscow, after first studying under W.W. Alpatov. Gause worked initially as a biologist on population structure and the dynamic interactions of microorganisms and then later became a researcher on antibiotics such as Gramicidin S, which he discovered in 1942 and which was then used during WW2. He eventually received the Stalin Prize for his antibiotic discovery, and his research in this field was considered so important that he was spared the Lysenkoite persecution that affected some of his Soviet biologist colleagues.

The nineteenth-century achievements in Russian science had reached its peak in the work of D.I. Mendeleev, the inventor of the periodic table of chemical elements, but many other Russian scientists made notable contributions across both the nineteenth and the early twentieth centuries. As the work of Gause suggests, Russian contributions to experimental biology were also significant, as epitomized by the worldwide reputation of physiologist I.P. Pavlov (Vucinich 1970, pp. 298–313). Some other Russian scientists in the first half of the twentieth century also contributed to work on aspects of population dynamics such as plotting population density (Barnett 2011, pp. 61–63), and this field generally remained outside of the more politically contentious areas of Soviet science that were

negatively affected by the growth of Stalinist repression at the end of the 1920s.

### Gause's Law

In his well-known book *The Struggle for Existence* (1934), Gause attempted to provide aspects of a mathematical theory of the struggle for existence. He started from three generalizations of the phenomena of species multiplication. These were (1) multiplication occurs theoretically by geometric progression; (2) in reality, multiplication is subordinate to the rule of inertia; (3) small organisms multiply more rapidly than larger organisms (Gause 2019 [1934], p. 8).

As Gause explained about his approach to population dynamics, in his view, the growth of each species depended in part “on the unutilized opportunity for growth at that moment” (Gause 2019 [1934], p. 89): each species possessed certain specific coefficients of utilizing this opportunity in relation to the particular environment it resided in and in relation to the actions of the other species within this environment. Gause expressed his basic result as follows: the rate of growth of two species in a mixed population is determined by the absolute potential increases in the two populations multiplied by the comparative degree of realization of the increases (Gause 2019 [1934], p. 47).

Another concept outlined by Gause was the intensity of the struggle for existence, measured by the resistance needed to be overcome in order to increase the number of individuals by a unit in a given period of time. He suggested that, contrary to what might initially be expected, in many cases at least, the better were the environmental conditions for sustaining the different species involved, the more intense was the struggle for life, and the greater was the percentage of individuals of a given species who subsequently perished (Gause 2019 [1934], p. 14).

In the empirical sections of the book, Gause reported the results of several experiments that he had conducted with simple organisms undertaken in order to study how the populations of different organisms interacted with each other in specific

shared environments. For example, as has been outlined about his experiment with yeast:

Using the yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces kephir*, Gause unequivocally demonstrated the importance of interspecific competition in the interactions between species. These yeasts differ in their relative intensities of oxidation and fermentation. *Saccharomyces cerevisiae* is able to reproduce rapidly in the absence of oxygen, while the growth of *Schizosaccharomyces kephir* under anaerobic [oxygen-deficient] conditions is exceedingly slow. In the absence of other species ... Over time, it was predicted that *Schizosaccharomyces* would be excluded by *Saccharomyces*. (Bonsall 2002, p. 923)

As Gause explained, whether the first species would supplant the second (or vice versa) in any competitive context also depended on their respective inherent rates of growth and their maximal physical masses, the latter being known from separate studies of their individual growth potentials (Gause 1932, pp. 391–392).

In addition to yeasts, Gause experimented with different species of *Paramecium* and *Didinium* (unicellular ciliates), namely, *Paramecium aurelia*, *Paramecium caudatum*, and *Didinium nasutum*. In one experiment he introduced two species of *Paramecium* into containers with a bacterial culture that was a food source. After a few days, one of the species invariably became extinct as it was not able to compete with the other for access to the bacterial culture, thus verifying Gause's law in this particular instance. As Gauss explained: "*if we know the properties of two species growing separately ... then connecting these values into a theoretical equation of the struggle for existence we can calculate in what proportion a certain limited amount of energy will be distributed between the populations of two competing species*" (Gause 2019 [1934], p. 89; italics in the original). This links to the rate of the stream by which a population completely corners the food resources.

A classic example of Gause's law in action is MacArthur's warblers, which are five species of insectivorous wood warblers in Maine and Vermont (USA) that occupy exactly the same forest breeding area, which are named after Canadian ecologist Robert MacArthur (1930–1972). Although this location-specific coexistence might appear to

violate Gause's law, in fact, MacArthur discovered that the feeding positions of the birds on the trees they inhabit are divided into 16 different zones or positions, which each species confining their feeding activities to specific designated zones (MacArthur 1958). The foraging behaviors of the warblers also differ in the same structured and specialized manner, thereby corresponding fully to the competitive exclusion principle.

## Grinnell's Axiom

Although the competitive exclusion principle is universally referred to as Gause's law, the first person to clearly specify it was Joseph Grinnell (1877–1939), an American field biologist and zoologist. Grinnell explained that "we never find two 'subspecies' breeding in the same faunal area," and "Two species of approximately the same food habits are not likely to remain long evenly balanced in numbers in the same region. One will crowd out the other" (Grinnell 1904, p. 373, 377). This was a more concise statement of Gause's law than was originally provided by Gause himself in his various publications from the early 1930s (Gause 1932, 2019 [1934]), and it has subsequently been named as Grinnell's axiom.

Grinnell maintained that which species would eventually triumph in the case of an indigenous species versus an invader species depended on the specifics of the particular case under view, and which species was best fitted to the local conditions as they existed at the time of the invasion. Small changes in local conditions could give an invader species an advantage in some instances, facilitating their victory in the competitive battle for survival, while if the indigenous species was still best adapted to local conditions due to its longer exposure to them, then they would successfully see off the competitive challenge.

## The Logical Status of Gause's Law

However, the theoretical nature or logical status of Gause's law has been subject to debate, primarily because there are various acknowledged

exceptions to it (the prevalence of natural coexistence of species in some verified instances: see the next section below). This means that it is not a strictly observed, *a priori*, or universal causal law; instead, it has been characterized variously as a broad empirical regularity, a *ceteris paribus* law, or a coexistence law.

In addition, the operation of Gause's law in any particular instance may be specific to the example under review. For instance, in one case (an invasive ant species), it was reported that there was no simple relationship between the degree of aggression exhibited by the invaded species involved and the taxonomic remoteness of the intruder species (de Vroey 1979). In some instances it might be the case that a specific homologous range of species may coexist in the same niche, but others outside this range do eventually become out-competed, or in other instances, it might be the case that closely related species can have very similar niches.

Some interesting and unusual results have also been reported regarding the expression of Gause's law. For example, one set of experiments repeatedly pitted two species of flour beetles against each other, with the result that one species always eventually eliminated the other, but it was not always the same species that had triumphed (Hardin 1960, p. 1293). This was interpreted to demonstrate that small variations in the initial conditions and/or small changes in the developing circumstances could sometimes have decisive effects on the outcome, this being a population dynamics version of the well-known butterfly effect.

Some of the various factors that have been specified as having an impact on the final outcome are initial species numbers, numerous environmental factors, comparative competitive abilities, resistance to disease, the degree of genetic diversity, and many others. As has rightly been explained on the general applicability of Gause's law:

To assert the truth of the competitive exclusion principle is not to say that nature is and always must be, everywhere, "red in tooth and claw." Rather, it is to point out that *every* instance of apparent coexistence must be accounted for. Out of the study of all such instances will come a fuller

knowledge of the many prosthetic devices of coexistence, each with its own costs and its own benefits. (Hardin 1960, p. 1297)

As is well articulated in this paragraph, the question of environment-sharing coexistent species, or apparent exceptions to Gause's law, now requires consideration in more detail.

## Exceptions to Gause's Law

The best known exception to Gause's law is the so-called plankton paradox. According to Gause's law, since all plankton species live on a very restricted set of marine resources in a given oceanic area, only a small number of plankton species should be able to coexist in this environment over the long term. In fact, large numbers of plankton species thrive together within limited regions of the open ocean (Hutchinson 1961).

One aspect of the solution to the plankton paradox may be the already-outlined notion that in a given ecosystem – in this case an ocean/marine ecosystem – a certain range of very similar species may coexist. This could be (for example) because of the prevalence of environment-specific features such as spatial heterogeneity, chaotic fluid motion, and/or equilibrium-deficient systems that produce chaotic oscillations, rather than stable equilibrium points, in given ocean/marine environments (Scheffer et al. 2003). The oceanic environment is a very different ecosystem than that occupied by most land-based animal species, so the rules underlying the competitive behavior of ocean-based species might also be very different in some instances.

Another potential exception to Gause's law is predator-mediated coexistence, which occurs when selective predation facilitates the coexistence of different prey species that would otherwise eradicate a proportion of them by means of the standard operation of Gause's law. The existence of aggregated distribution, or highly uneven and widely separated aggregated regional distribution patterns, and/or environmental heterogeneity, may also aid some competitor species exemptions from Gause's law. Character

displacement, or trait evolution to lessen resource competition, is another explanation that can be seen to apply in some instances. In general, the existence of various different exceptions to Gause's law is firmly established in the literature, but this does not invalidate the law itself as a substantiated *ceteris paribus* law.

## Gause's Law and the Evolution of Animal Cognition

A cognitively enhanced version of Gause's law could be articulated as follows: no two species with very similar ecological niches, similar morphologies, and similar food sources, but with some different cognitive abilities, can coexist in a state of stable equilibrium, as the species with the superior cognitive function in key areas of behavior will ultimately triumph. A particular species competitive advantage could also include a cognitive element but not be limited to this area alone. It can consequently be asked whether interspecies competition can sometimes act as a factor driving the evolution of cognitive function: a form of competitive co-evolution or reciprocal evolution may also lead to competitive displacement.

Certainly, co-evolution between predators and prey often involves an evolutionary arms race between predating capture skills and predator avoidance skills, these skills sometimes being partly cognitive in nature (Barnett 2019). One key set of cognitive skills in this case is the development of an understanding of individual intentionality and agency in relation to the progression of predator-prey interactions, skills such as gaze direction detection mechanisms, movement projection deception abilities, predator-prey intention awareness, and fast and frugal decision-making abilities (Barrett 2005, p. 202). Even if two closely situated species are not in a predator-prey relationship, their interactions can still involve direct cognitive competitions and subsequent neurological evolutions, and the outcomes of these iterated interactions might then in some circumstances produce the extinction of one of the species involved, in accordance with Gause's law.

An additional element to any cognitive competitions between competing species residing in the same environment or ecological niche is the hypothesized existence of the cognitive niche, or a repertoire of simple decision-making strategies that utilize regularities in the local environment to assist in the decision-making process (Marewski and Schooler 2011). In relation to predator-prey interactions, these cognitive niches can be seen to facilitate the fast and frugal decision-making abilities that are required to increase an individual animal's chances of victory and/or survival.

## The Application of Gause's Law to *Homo Sapiens*

Gause's law has in certain cases been applied to some prehistoric types of human society. For example, it has been suggested that two or more hunter-gatherer groups living within the same ecological niche will sometimes come into direct conflict over available resources, leading in some instances to the departure/vanquishing of one or more of the competing hunter-gatherer groups, in accordance with Gause's law (Fog 2017).

The theory of kin selection also predicts that contemporary minority ethnic groups will show higher degrees of in-group solidarity than is seen among the wider general population in particular countries (Salter 2007). This suggests not that ethnic groups supplant other indigenous populations via Gause's law but that ethnic nepotism is a real phenomenon that has an effect on both wider social cohesion and local business structure, for example, through the development of ethnically homogeneous housing clusters or minority-dominated trading groups (Light and Karageorgis 1994). Here the competitive exclusion principle is functioning within specific geographical areas and particular business sectors of the economy, rather than between whole population groups.

Gause's law has also been applied to the competition between very similar businesses in the same sector in a market economy, with large

companies tending to takeover or acquire smaller rival companies producing very similar products in some circumstances (Henderson 1989). However, as with all these types of extension of Gause's law to elements of human societies, the parallels that are here being posited are only very inexact ones, and various modifications to the underlying assumptions are usually necessary. Also, the various exemptions from Gause's law that have already been discussed might apply to some instances of *Homo* competitive activities.

## Conclusion

Gause's law, albeit a *ceteris paribus* law with various highlighted exceptions, has proved itself to be an important contribution to population dynamics and also to ecological thinking more generally. However, although Gause's law is now universally defined as the competitive exclusion principle (CEP), Gause himself did not initially name it as such, and it has been suggested that a loose formulation of the idea can be found in Charles Darwin's *Origin of Species*: with similarity of habits and constitutions in species, the struggle between them is generally more severe (Gause 2019 [1934], p. 15; Darwin 1872 [1859]). And it was Joseph Grinnell who had earlier specified a more concise version of Gause's law in an article that was published in 1904.

Even so, the relevance of Gause's law as a *ceteris paribus* law to the contemporary world still remains, and he was still personally defending it almost four decades after he first presented it (Gause 1970). Therefore, Gause's book *The Struggle for Existence* should be regarded as an enduring classic of mathematical biology, population dynamics, and behavioral ecology that also has significant relevance outside the narrow confines of the mathematical modeling of abstract biological processes.

## Definitions

Gene expression is the process of decoding the information stored in the DNA (2-deoxyribonucleic acid) to its functional forms.

## Heredity and Gene Expression

In the 1860s, Gregor Mendel showed that genetic information transfers from parents to offspring in discrete units, later named genes, that confer heritable traits such as morphological features including flower color or plant height. The exact chemical nature of the genetic material was unknown until the mid-1940s. Two possible candidates, DNA and protein, were always found together in the chromosomes of the nucleus – the center of hereditary information of the cell. Genes affect phenotypic traits was known since Mendel's work. Compelling evidence also suggested that genes affect enzyme functions and control the metabolic activities of an organism. In the early 1900s, Archibald Garrod examined patients excreting homogentisic acid (alcapton) in their urine that turned black upon exposure to air. This disorder (alcaptonuria)

follows a pattern of Mendelian inheritance. Garrod concluded that in the affected individuals, the gene responsible for the breakdown of alkapton was missing or compromised. On the same note, Beadle and Tatum performed random mutagenesis in *Neurospora* and showed that genes act stepwise to drive metabolic reactions. They generated *Neurospora* mutants defective for the distinct steps of metabolic pathways involved in vitamin biosynthesis (Beadle and Tatum 1941). This sparked their “one gene-one enzyme” hypothesis.

DNA was widely accepted as genetic material in the mid-1940s and confirmed by Hershey and Chase in 1952. In 1953, a model for the structure of the DNA was proposed (Watson and Crick 1953). Two sugar-phosphate antiparallel strands of DNA pair up with each other through hydrogen bonding of nitrogenous bases. These nitrogenous bases are adenine, guanine, thymine, and cytosine. Adenine pairs with thymine with two hydrogen bonds, while guanine forms three hydrogen bonds with cytosine. The pairing of complementary nucleotides between two DNA strands provides a simple mechanism for copying the genetic information. When separated, each strand

provides the template for creating a complementary daughter molecule to pass on to the next generation (Fig. 1). It is the order of bases that has the instructions for the development of a complete organism from a single fertilized cell. In 1957, Vernon Ingram associated a defect in the hemoglobin gene which expresses a protein with a single amino-acid change, causing sickle-cell anemia. It was conclusive evidence that hereditary information in DNA is expressed via the synthesis of proteins that act to determine morphology and physiology of an organism, although it was still unclear where and how the DNA expressed proteins in the cell.

### Gene Expression: Information Flow from DNA to Proteins

In the 1950s, cellular protein synthesis was monitored by radioactively labeled amino acids. When such a cell was lysed and the contents fractionated by centrifugation, the radioactivity always appeared in the RNA-rich fraction. This fraction contains small electron-dense structures known as microsomal particles, later named ribosomes.

#### Gene Expression,

##### Fig. 1 A molecular structure of the DNA.

DNA consists of two complementary strands that are joined through hydrogen bonds and form a double helix. The hydrogen bonds are formed between the nitrogenous bases that are attached to a sugar-phosphate backbone: adenine pairs with thymine and cytosine pairs with guanine. In DNA, the sugar is 2-deoxyribose. Chimera structure visualization tool was used to draw image from Protein Data Bank (PDB) database structure, accession number – 1d65

Ribosomes were assumed to be the sites of protein synthesis (Hoagland et al. 1957) and were found to be. Obviously, ribosomal RNA (rRNA) was thought to carry information from DNA to make protein. However, this possibility was ruled out because all ribosomes have an identical rRNA composition, contrasting the variety of RNAs required for the synthesis of various proteins. Meanwhile, Francis Crick made the following suggestions on protein synthesis in his seminal paper (Crick 1958): (1) The sequence hypothesis proposes that the order of bases in the DNA determines the order of amino acids in the protein. (2) The central dogma speculates that RNA formation precedes protein formation and not vice versa. It means that once the information has passed into protein, it cannot reverse. (3) The adaptor hypothesis assumes that either protein or nucleic acid acts as adaptor to carry individual amino acids for protein formation. These ideas were based on the experimental results of the last 10 years. In 1959, Weiss and Gladstone incubated radiolabeled cytidine 5'-triphosphate (CTP) in an

extract of rat hepatocyte nuclei to find a large fraction of labeled CTP in RNA which was incorporated in a DNA-dependent manner (Weiss and Gladstone 1959). The enzyme responsible for this activity is now recognized as a RNA polymerase, and the process is called transcription (Figs. 2 and 3). In 1961, with isotopic labeling experiments on infection of *E. coli* with T4 phage, it was found that the phage proteins were made using an intermediate molecule synthesized from its DNA by employing the bacterial ribosomes. This intermediate molecule was recognized as an RNA species with a high turnover, indicating its unstable nature (Brenner et al. 1961). This special RNA is termed as messenger RNA (mRNA) since it carries a complementary sequence of the DNA template and is transported as messenger from the nucleus to the ribosomes, where its base sequence was utilized for protein synthesis in a process called translation (Jacob and Monod 1961). After protein synthesis, the mRNA would leave the ribosomes, making way for other potentially different mRNAs.

**Gene Expression, Fig. 2 RNA polymerase II in transcription pre-initiation complex.** DNA double helix (in red color) is bound by five transcription initiation factors (in cyan color) in the upstream (indicated) of TSS. TATA box-binding protein (in yellow) is bound to the promoter region. RNA polymerase II and its pre-initiation complex subunits are shown in gray and purple,

respectively. In the downstream region (indicated), DNA helicases (forest green) and other associated factors are unwinding DNA for transcription elongation. The figure reveals the tight regulation of transcription initiation by several proteins. **Transcription in Eukaryotes**

A typical eukaryotic cell, particularly in multicellular organisms, expresses only a subset of genes present in its genome. This expressed subset determines the cellular identity and functionality. Often the expression pattern is maintained in the daughter cells to ensure tissue homeostasis. In addition, most cells tune global gene expression in response to extracellular and intracellular signals without altering their DNA. For instance, when exposed to high temperature, cells will express genes involved in heat resistance. Gene expression is a highly energy-demanding process, and in principle, all steps involved can be regulated. However, most genes are regulated during transcription initiation by a special class of DNA-binding proteins called transcription factors (TFs), along with several other associated proteins (Fig. 2). A mechanistic detail of the transcription regulation mainly comes from the structural studies of RNA polymerase and accessory proteins by Kornberg and coworkers (Murakami et al. 2015).

The upstream regions of genes contain regulatory sequences where TFs and the RNA polymerase bound. Transcription begins when RNA polymerase gets recruited to the region of the

gene called promoter, which is generally located 25–30 nucleotide bases upstream of the transcription start site (TSS) (Fig. 2). RNA polymerase is recruited there by TFs, also called *trans*-regulatory elements, that recognize and bind to the upstream regulatory DNA sequences. One of the most common promoter regions is called a TATA box, reflecting the presence of adenine and thymine nucleotides. Mutations either in regulatory sequences (also called *cis*-regulatory elements) or the TFs may affect transcription. There is a certain variability in the promoter elements, but they are invariably bound by the general TFs needed for transcription and eventually by RNA polymerase that synthesizes the mRNA. In recruiting the transcription machinery, general TFs are often assisted by specific TFs. The latter can enhance or attenuate the transcription of a gene, even if they bind thousands of nucleotides away from the TSS. These TF-binding sequences are called enhancer elements. They mainly regulate genes that define the function of a cell, such as hemoglobin gene which must be expressed only in erythrocytes. Specific TFs rarely regulate housekeeping genes that are required in every cell for performing general functions such as metabolic maintenance

or building cytoskeletal components. Housekeeping genes are expressed constitutively.

Once the RNA polymerase is recruited, it moves along the DNA template strand in 3–5' direction and synthesizes a strand of RNA consequently in 5–3' direction complementary to the DNA (Fig. 3). RNA and DNA are very similar nucleic acids, except for the pentose sugar which lacks a hydroxyl group in DNA, and a uridine (instead of thymidine) is inserted in the RNA by RNA polymerase based on its complementarity with adenine of the DNA template.

### Posttranscriptional Processing

mRNA is short lived, distinct from other RNAs, and transported from the nucleus to the cytosolic ribosomes. It would be degraded quickly in ribonuclease-rich cytosol. Therefore, mRNA undergoes processing at both ends before leaving the nucleus. The 5' end is capped with 7-methylguanosine, and a long sequence of adenines is attached to the 3' end (poly-A tail). Poly-A tails are unique to mRNAs and absent in the DNA template. Moreover, a typical eukaryotic gene is composed of coding regions called exons and intervening regions (known as introns) that are incorporated into pre-mRNA but not translated into proteins. While the order of the exons is maintained through the removal of introns (splicing), some exons may be removed along with the introns in the process of alternative splicing. It results in different gene products from the same gene. This challenges Beadle and Tatum's one gene-one enzyme hypothesis. It creates several functional variants from the same gene, expressed in different contexts. mRNA is bound by several proteins called messenger ribonucleoprotein particle (mRNP) which are transported into cytosol through nuclear pores.

### Translation in Eukaryotes

In the cytoplasm, the mRNP will be remodeled, and binding of translation initiation factors to the 5' methylcytosine cap of the mRNA will initiate translation. The small ribosomal subunit carrying

a methionine-charged tRNA moves along mRNA until it encounters an AUG sequence also called a start codon. Subsequently, a large ribosomal subunit replaces initiation factors to elongate the polypeptide sequence. Ribosomes and amino-acid-charged tRNAs read the mRNA in a frame of three nucleotide bases (called a codon, a unit of genetic code) at a time and transfer amino acids from tRNA to the nascent peptide according to the sequence of the mRNA (Crick 1963; Nirenberg and Leder 1964). The tRNA has a base triplet, called as anticodon, that pairs with its matching mRNA codon. Upon binding of codon and anticodon, the amino acid is transferred from the tRNA to the nascent peptide. Peptide elongation stops when one of the three termination or stop codons occurs in the mRNA sequence. The nascent peptide will be folded during its synthesis with the help of chaperone proteins. Misfolded proteins are degraded immediately, while many proteins undergo posttranslational modifications. This may include their transport into specific cell organelles which require targeting sequences that are cleaved at the destination. Many proteins are covalently modified by the addition of various chemical moieties such as phosphorylation or methylation in order to function.

### Importance of Studying Gene Expression

Gene expression enables an organism to mount a high fidelity response to the existing environment by expressing a subset of genes. The various possible combinations allow great diversity in gene expression from the same piece of DNA. It is the differential gene expression which gives rise to numerous cell types from a single cell. Studying gene expression has brought on the era of biotechnology, high-yielding crops in agriculture, and diagnostic biomarkers for several diseases. Any malfunction during gene expression could manifest in a life-threatening condition. For example, several antibiotics proved to be lethal weapons against bacteria as they inhibit protein synthesis. Many diseases such as cancer result from altered functions of TFs. The modern techniques like gene expression profiling which

measure the expressions of mRNAs in the cells have been crucial in understanding cellular responses to various conditions.

## Definitions

The measurement of the expression levels of the genes present at a particular time point in the cell.

## Introduction

In 1953, Watson and Crick proposed the structure of the DNA – the blueprint of the cell (Watson and Crick 1953). DNA is made up of two sugar-phosphate strands which run antiparallel to each other, paired up with each other through hydrogen bonding between the four nitrogenous bases which protrude from each strand (Fig. 1). DNA sequence contains functional regions called as genes, which confer phenotypic traits to an organism.

DNA transcribes its gene containing regions into various types of functional RNAs and messenger RNAs (mRNAs). mRNAs get translated

**Gene Expression Profiling, Fig. 1** A double-stranded DNA molecule. Two sugar-phosphate backbones represented by straight black lines form the side rails of the ladder-like structure of the DNA. Four nitrogenous bases: adenine (A), thymine (T), guanine (G), and cytosine (C) which protruded from these backbones and represented by rectangles are the rungs of the DNA ladder. Small arrows indicate the direction (5' to 3') of the sugar-phosphate backbones

into different types of proteins. The overall process is called gene expression (Fig. 2).

Generally, in all the cells of higher organisms like human, the DNA of each somatic cell is the same. The distinct functions and appearances of various cells in animals and plants is due to the expression of different types of proteins. For example, the cells of the human eyes are enriched in opsin proteins, which enable us to see the world, while cells of the tongue are enriched in G-protein-coupled receptors for rejoicing different kinds of food. All this happens because different genes get activated in different cell types and express different forms of proteins in spite of having the same DNA. The total number of genes expressed in an organism is called transcriptome. Measuring the expression levels of all genes by quantification of all RNA species in the cells at a particular time point is called gene expression profiling. Gene expression profiling provides a snapshot of the physiological state of the cells at a particular time point. In the tissue of multicellular organisms, gene expression will change with the age, diseases, environmental

changes, and during stress, e.g., exposure to toxic chemical compounds. Damaged or diseased cells often have very different gene expression profiles compared to their healthy counterparts. Comparison of the expression profiles of healthy and diseased/infected cells often leads to an understanding of the impaired gene functions in diseases. Therefore, gene expression profiling is changing the course of future medicine. Gene expression profiling may provide more assistance in understanding disease and cure than the biopsies (Heinloth et al. 2007).

Studies on investigating the abundance of several mRNAs at large scale commenced in the late 1970s using the Sanger sequencing technique (Sim et al. 1979). This technique evolved over time and extended to simultaneous expression profiling of almost every gene of the cell. In this chapter, we shall give an overview on the three most successful gene expression profiling techniques.

## Expressed Sequence Tags

In eukaryotes, precursor mRNA (pre-mRNA) is transcribed from the DNA template in the nucleus, and undergoes posttranscriptional modifications before being exported to the cytoplasm. Pre-mRNA is composed of the 5' untranslated region (UTR) before the transcription initiation codon, varying number of exons (coding regions), and introns (noncoding regions), and a 3' UTR after the termination codon. The 5' end is capped with 7-methylguanosine while 3' is polyadenylated (carrying a poly-A tail) (Fig. 2). Introns are removed (during splicing) to create the mature mRNA by retaining different exons for different transcript-variants by alternative splicing of exons. The cDNAs (complementary DNAs) obtained through reverse transcription of mRNAs are regarded the first-strand cDNAs. Reverse transcriptases like the one from the avian myeloblastosis virus (AMV) create a hairpin loop at the 3' end of the first-strand cDNA which can then be used as a primer for the synthesis of second strand of cDNA as shown in Fig. 3 (Efstratiadis et al. 1976). In the end, special

**Gene Expression Profiling, Fig. 2 Gene expression in eukaryotes.** The two strands of DNA are represented by a pair of grey- and white-colored thick lines. Grey represents the exon and white marks the intron. The thin grey-and-white-colored line represents mRNA. Pre-mRNA (premature messenger RNA) is having exons, introns, 3' polyadenylated or poly-A tail, and 5' methylguanosine

cap, which is shown by the circle. 5' cap and 3' poly-A tail are added into the primary transcript later on. 5' and 3' UTRs (untranslated regions) are omitted from the diagram for simplicity. mRNA (mature messenger RNA) is similar to pre-mRNA but lacks introns. Protein is represented by a bunch of arrow heads

**Gene Expression Profiling, Fig. 3 Double-stranded cDNA synthesis.** The thin line represents mRNA. mRNA is shown with two exons, the 3' polyadenylated tail, and 5' methylguanosine cap, which is shown by the circle. Poly-deoxythymidylate or poly (dT) containing primer anneals

to the 3' end of mRNA and is used for reverse transcription. The 3' hairpin at the first-strand cDNA acts as primer for the synthesis of second strand of cDNA. S1 nuclease cuts the hairpin to create the double-stranded cDNA with free ends

nucleases (such as the S1 nuclease) cleave the hairpin to obtain double-stranded cDNA with free ends that can be cloned into plasmids for generating cDNA libraries. cDNA clones are sequenced arbitrarily from both 5' and 3' termini without completing the full length. Thus, the reads

output generates 5' and 3' expressed sequence tags (ESTs), respectively (Fig. 4). As mRNA is fragile, the cDNA represents its different length forms in the cDNA library. Hence, the reads of ESTs are overlapping with each other as shown in Fig. 4 (Nagaraj et al. 2007). EST was one of the best

**Gene Expression Profiling, Fig. 4 Redundancy in ESTs.** (I) The two strands of cDNA (cloned in the plasmid) are shown, representing two exons. The poly (dA) and poly (dT) tails are shown. Thin arrows indicate the direction of

the sequencing. (II) The 5' and 3' ESTs are drawn parallel (dotted lines) to the original cDNA sequence. ESTs reads are redundant and overlapping with each other

techniques in earlier days to study high-throughput gene expression and novel gene discovery (Nagaraj et al. 2007). For instance, in 1991, Adams et al. were able to identify 337 novel genes (ESTs) expressed in the human brain (Adams et al. 1991).

The number of genes studied through ESTs are limited since the procedure involves cloning of cDNAs. With the availability of many completely sequenced genomes since the late 1990s, doors were opened to another gene expression profiling technique called DNA microarray, which remains useful even through the next-generation sequencing era.

## DNA Microarrays

Through DNA microarrays, the expression of thousands of genes can be studied without much manual labor of cloning and sequencing (Schena et al. 1995). Information obtained through ESTs, genome projects, and other genomics techniques is used to create single-stranded oligonucleotides which represent known sequences of genes. These oligonucleotides can be fixed on a glass chip, literally forming microscopic spots of DNA microarrays. DNA microarrays work by the principle of hybridization of two complementary strands of DNA (Fig. 1). In short, a strand of DNA from a known gene is fixed to a particular

spot on the microarray chip and cDNA obtained through reverse transcription (Fig. 3) from the sample mRNA is used to hybridize with the strand fixed on the chip. Reverse transcription is performed with fluorescently labeled nucleotides, so that the hybridized DNA can emit light which can be detected and read under LASER irradiation and thus can be quantified. The unhybridized sample DNA is washed away.

Since 1995, DNA microarray was the method of choice to understand diseases and specific gene expression dynamics of cells, tissues and organs (Schena et al. 1995). DNA microarrays have also been of great help in understanding cell cycle, developmental stages, metabolism, disease diagnostics, and classification of various cancers. However, the method can be applied for profiling expression of known genes only.

## RNA Sequencing

In order to make DNA microarrays work, enough information about the sequences of genes is required. When gene information is not available for a species of interest, gene expression profiling can be performed by RNA sequencing (RNA-seq). RNA-seq utilizes next-generation sequencing technology (NGS) for gene expression profiling. NGS technology is based on massively parallel sequencing-by-synthesis of DNA,

**Gene Expression Profiling, Fig. 5 Clonal expansion in next-generation sequencing.** (I) The grey line is the cDNA and the white and black stripes at both ends of the line represent the adapters of the cDNA. At the right-hand side, the white stripe represents the oligonucleotide fixed to the solid surface which is complementary to one of the white adapter sequence. The arrow indicates the direction

of the polymerization. (II) One new strand complementary to the cDNA got synthesized. (III) The second adapter (black) pairs with its counterpart attached sequence (bridge amplification). The arrow indicates the direction of the polymerization. (IV) Another strand is synthesized. (V) During denaturation, the two strands separate

as explained below in more detail (Ju et al. 2006). The protocol for preparing the cDNAs is very similar to the one described before (and in Fig. 3) for ESTs. Depending upon the specific requirements, a particular type of RNAs (mRNA, transfer RNA, ribosomal RNA, and small noncoding RNA) is isolated. Generally, mRNA is enriched by employing polythymidylate or poly (T) magnetic beads that bind to poly-A tails unique to mRNA. The enriched mRNA is used to produce double-stranded cDNA through reverse transcription (Fig. 3). DNA adapters of known sequences are ligated to both ends of the cDNAs in a process called tagmentation. These adapters can hybridize to known complementary sequences attached in millions to a solid surface and DNA polymerase can synthesize the complementary strand of DNA (Fig. 5I and II).

In the second step of bridge amplification, the new strand complementary to the one synthesized in the first round can be assembled where the sequence complementary to the second adapter works as the primer as shown in (Fig. 5III and IV). These steps repeat and clonal expansion of the cDNAs takes place. For sequencing, the primers complementary to the adapter sequences are used for DNA polymerization with four nucleotides. Each of the four nucleotides is labeled with a fluorescent dye of a different color. Upon

incorporation of a nucleotide to the nascent strand, its fluorescence is captured by a camera, and the fluorescent tag subsequently cleaved enzymatically. Only after cleavage of the tag, the next nucleotide can be incorporated. Millions of sequences corresponding to the forward and reverse strands of DNA can be read out on the screen as the reaction progresses. Bioinformatics tools are used to assemble reads and compute the abundance of each mRNA in the initial sample using sophisticated mathematical and statistical techniques (Trapnell et al. 2012).

The advantage of RNA-seq over previous techniques is manifold. RNA-seq can be used for gene expression profiling of any organism. RNA-seq based quantification of gene expression levels highly correlates with the transcript abundance measured by low throughput experiments. This reflects the high accuracy of the method (Mortazavi et al. 2008). It has turned out to be most accurate gene expression profiling technique so far, and a real game changer in understanding the complexity of transcriptional regulation.

## Gene Flow

Neelabh

Department of Biotechnology, SR Institute of Management and Technology, Lucknow, Uttar Pradesh, India

Department of Zoology (MMV), Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

## Synonyms

[Allele flow](#); [Gene migration](#)

## Definition

The migration/movement or transfer of the genetic variation from one population to another is called gene flow.

## Introduction

Gene flow is the elementary agent of evolution responsible for the dispersal of genes between two populations of the same or different species, followed by the successful establishment of the immigrant genotypes in the new population (Woodruff 2004). Gene flow between two populations of the same species is mediated by reproduction and vertical gene transfer from parent to offspring. Gene flow between two different species, for instance, from a bacteria or virus to a higher organism or an endosymbiont to the host, occurs due to horizontal gene transfer (Choudhuri 2014). Conclusively, when the gene flow occurs within a population, it can increase the genetic variation between the populations, whereas gene flow occurring between genetically distant populations can reduce the genetic variations between them (Choudhuri 2014). When gene flow is hampered, it results in an increase in inbreeding, which can be measured by the inbreeding coefficient (F). For instance, the Black Footed Rock Wallaby has several

populations that are strongly isolated due to geographical barriers and, therefore, favor inbreeding (Eldridge et al. 1999). Another example of hampered gene flow is the young female chimpanzees, which are incapable of emigration from their natal social group due to the loss of habitat in the surrounding countryside. Therefore, they would experience increased inbreeding.

A lot of events can result in gene flow; for instance, pollen is blown away by the wind to far-off regions, blue-eyed people migrating from Sweden to a city in Mexico where all brown-eyed people live, a group of women from West Africa where Malaria is present mate with a group of Europeans, etc. A diagrammatic representation of the migration of a brown-colored beetle to the population of green-colored beetles has been shown in Fig. 1.

All these events would result in the induction of genetic variations if the gene versions in question were not present at these places before (UCMP 2020). However, if the gene flow rate is high enough, then the two populations would have equivalent allele frequencies and therefore, would effectively be considered one population. Because gene flow can be facilitated by the physical proximity of the populations, gene flow can be restricted by physical barriers separating the populations. Incompatible reproductive behaviors between the individuals of the populations also prevent gene flow.

Gene flow is often gender-prejudiced and is restricted to specific stages of the life cycle.

There are several factors on which gene flow depends. It is likely to be lower in species having low mobility or dispersal, small population size, long distances between populations, and occurring in fragmented habitats (Hastings and Harrison 1994; Hamrick and Godt 1996). Mobility has a significant role to play in the migration rate. Individuals having high mobility tend to have high migration potential. However, in the case of plants, although they are less mobile than animals, yet their genetic content can be transferred to a great distance by animals or wind.

### Examples of Gene Flow

Around 15,000 years ago, all dogs were basically wolves. But, some of the pre-dogs scavenged near the human settlements and came closer to humans, whereas the wolves moved further away from the human-occupied areas. Dogs served humans with vermin control, waste removal, or a hunting guide. Humans, in turn, provided shelter and food to the dogs. Gene flow, in the case of dogs, can be assumed in a condition where one dog from a specific population can breed with other pure breeding populations. This would result in the introduction of the new alleles to the group, for example, Labradoodle, half-Beagle, Puggle, etc. (Pilot et al. 2015).

Another example can be of the red parrots having brought to a remote area of the jungle in which originally only the blue parrots lived. This

**Gene Flow, Fig. 1** Brown-colored beetle migrates from its original population to the green-colored population. (Adapted from UCMP 2020)

would introduce color variations into the gene pool of the parrots living in the jungle (Your Dictionary 2020).

Red parrots are brought on an expedition to a remote section of jungle with only blue parrots, introducing color variation into the gene pool of jungle parrots.

Bacteria have a peculiar way of gene transfer. They make use of the horizontal gene transfer when it comes to the gene flow. In this process, the DNA passes between the organisms without the need for sexual reproduction. Most of the diversity seen today is a result of these gene transfers that took place millions of years ago (Biology Dictionary 2018). An example of the horizontal gene transfer in bacteria can be the transfer of the antibiotic resistance genes from one bacterium to the other. This gene transfer is the primary reason responsible for the growing resistance in bacteria against the currently used antibiotics.

## Conclusion

Gene flow, gene migration, or allele flow is an important mechanism responsible for transferring genetic diversity from one population to the other. When there is an obstruction or no transfer of genes between two populations, then it may lead to speciation. Migration and intermarriages between national and state communities are strong forces of gene flow. Conversely, geographical isolation and reproductive isolation play an essential role in limiting the transfer of gene flow.

## Synonyms

[Allele frequency](#)

## Definition

Gene frequency can be defined as the fraction or percentage of a population that carries allele (i.e.,

one type of a gene variant) at a particular locus (Gillespie 2004). It is also more appropriately known as allele frequency.

## Introduction

In population genetics, gene frequencies refer to the quantity of variation at a particular locus or across multiple loci. The gene frequency is different from the genotypic frequency in case of diploid organisms, although they seem to be related to each other, and gene frequencies are usually calculated from genotypic frequencies. The value of gene frequency always exists between 0 and 1. For example, if all of the alleles in the pea plant population were tall alleles (represented as “T”) and none of the alleles were dwarf alleles (represented as “t”), then the “T” allele frequency would be 100% or 1, and “t” allele frequency would be 0% or 0. However, if half of the alleles were “T” and half were “t,” then either of the alleles would have an allele frequency as 50% or 0.5.

## Calculation of Gene or Allele Frequency

Gene frequency calculations are dependent on the ploidy of the species. For a haploid organism like *E. coli*, the gene frequency of a particular nucleotide polymorphism (e.g., G vs. C) can be estimated by taking a sample of 1000 bacterial cells and analyzing them for the sequence variant of interest. Now, suppose if we found that 25 of 1000 are G, then the gene frequency of G allele =  $25/1000 = 0.025$  or 2.5% and the frequency of alternative allele C =  $975/1000 = 0.975$  or 97.5%. Moreover, another way to calculate the frequency of C allele can be simply as  $1 - p$  (where  $p$  = frequency of G allele), i.e.,  $1 - 0.025 = 0.975$ .

It is necessary to differentiate between gene and genotype frequencies in diploid organisms (Aquadro 2001), since in DNA of diploids, at a particular site, some chromosomal locus carry a G (in frequency  $p$ ) and some carry C (in frequency  $q$ ). Some individuals will have two Gs, some a G and C and some two Cs. Individuals with two copies of the same allele are called homozygotes (e.g., G/G or C/C), and

one with two different alleles is called heterozygotes (e.g., G/C). Genotype frequencies refer to the ratio or percentage of each genotype in the population sample. For one set of gene frequencies, many different types of genotypic frequencies can be possible: e.g., for  $p = q = 0.5$ , genotypic frequency could have 0.5 G/G, 0.0 G/C, and 0.5 C/C; or it could have 0.0 G/G, 1.0 G/C, and 0.0 C/C; or it could have 0.25 G/G, 0.5 G/C, and 0.25 C/C; the latter is what is expected with random mating and no selection, drift, mutation, or migration, i.e., the Hardy-Weinberg equilibrium genotype frequencies.

In a diploid, sexually reproducing organism, gene, or allelic frequencies for autosomal locus can be measured in either of two ways. The first way is simply by counting genes. Consider, for example, the phenotyping distribution of MN blood types (controlled by codominant M and N alleles) among 200 persons:

Type M (MM genotype) = 117

Type MN (MN genotype) = 69

Type NN (NN genotype) = 14

Since the homozygotes have two of a given allele and heterozygotes have only one, and since the total number of alleles is twice the number of individuals (each individual carries two alleles), we can calculate allelic frequencies in the following manner:

Frequency of M allele

$$= \text{Number of M alleles} / \text{Total number of alleles} \\ = (2 \times \text{Number of MM homozygotes}) \\ + (\text{Number of MN heterozygotes}) \\ / (2 \times \text{Total number of individual})$$

The expression “frequency of” can be shortened to  $f(X)$ . For example, the frequency of the M allele will be written as  $f(M)$ .

Then,

$$f(M) = p = 2(117) + 69 / 2(200) = 303/400 \\ = 0.76$$

and,

$$f(N) = q = 2(14) + 69/2(200) = 97/400 \\ = 0.24$$

Alternatively, because the frequencies of the two alleles, M and N, must add up to unity ( $p + q = 1$ ),  $q = 1 - p$  (and  $p = 1 - q$ ), if we know that  $p = 0.76$  and  $q = 1 - 0.76 = 0.24$ .

Another way of calculating the allelic frequencies is based on knowledge of genotypic frequencies, which in this example are:

$$f(MM) = 117/200 = 0.59$$

$$f(MN) = 69/200 = 0.34$$

$$f(NN) = 14/200 = 0.07$$

We derive an expression for calculating  $p$  and  $q$  based on genotyping frequencies as follows:

$$p = f(M) \\ = 2 \times \text{Number of MM} + \text{Number of MN}/2 \\ \times \text{Total Number} \\ = (2 \times \text{Number of MM}/2 \times \text{Total Number}) \\ + (\text{Number of MN}/2 \times \text{Total Number}) \\ = f(MM) + 1/2 f(MN)$$

$$q = f(N) \\ = 2 \times \text{Number of NN} + \text{Number of MN}/2 \\ \times \text{Total Number} \\ = (2 \times \text{Number of NN}/2 \times \text{Total Number}) \\ + (\text{Number of MN}/2 \times \text{Total Number}) \\ = f(NN) + 1/2 f(MN)$$

Thus, allelic frequencies can be calculated as the frequency of homozygotes plus half the frequency of heterozygotes as follows:

$$p = f(M) = f(MM) + (1/2) f(MN) \\ = 0.59 + (1/2) 0.34 = 0.76$$

$$q = f(N) = f(NN) + (1/2) f(MN) \\ = 0.07 + (1/2) 0.34 = 0.24$$

Allele and genotypic frequencies must always lie between 0 and 1.

## Calculation of Gene or Allele Frequency with Multiple Alleles

It employs the same rule that we used with two alleles. Suppose we have three alleles – A1, A2, and A3 – at a locus with dominance hierarchy  $A1 > A2 > A3$ . Let  $p$ ,  $q$ , and  $r$  represent the frequencies of alleles A1, A2, and A3, respectively. In this case, allelic frequency will be:

$$p = (2 \times A1A1) + (A1A2) \\ + (A1A3)/(2 \times \text{Total number of individuals})$$

$$q = (2 \times A2A2) + (A1A2) \\ + (A2A3)/(2 \times \text{Total number of individuals})$$

$$r = (2 \times A3A3) + (A1A3) \\ + (A2A3)/(2 \times \text{Total number of individuals})$$

To calculate expected genotype frequencies (if the population is in Hardy-Weinberg equilibrium), we use trinomial equation,  $(p + q + r)^2$ , which expands to  $p^2 + q^2 + r^2 + 2pq + 2pr + 2qr = 1$ .

Homozygotes will occur with frequencies  $p^2$ ,  $q^2$ , and  $r^2$ , and heterozygotes will occur with frequencies  $2pq$ ,  $2pr$ , and  $2qr$ .

## Conclusion

In nutshell, gene frequency or allele frequency is a measurement to show the genetic diversity of a population species or in other terms the abundance of its gene pool. Mathematically, it is expressed in terms of percentage or proportion. For example, *Merriam-Webster* defines this term as “the ratio of the number of a specified allele in a population to the total of all alleles at its genetic locus.” The subject of population genetics is concerned with the study of different factors or forces, which lead to the change in distribution of these gene frequencies for a given population.

## Definition

Gene mapping is allocating chromosomal location coordinates to a gene.

## Gene Map

Gene mapping is allocating chromosomal location coordinates to a gene. Mapping a gene helps to prepare a roadmap of genome and identify milestones in form of genetic markers. The genetic map of an organism gives an overview of gene arrangement in their chromosomes (refer Fig. 1). The gene maps are composed of markers which might be genes controlling visible phenotypic traits (classical markers) or molecular markers whose phenotype is revealed by using modern molecular biology techniques (e.g., DNA markers). In case of animals, gene mapping is used for all aspects of genome analysis and their improvement for benefit of human beings. Mapping of genes in farm animals, companion animals, laboratory animals, aquatic animals, insects, and primates, including humans provides comprehensive data which is used to elucidate origin, evolution, phylogenetic relationship; position of genes; function, expression, regulation, and sequence of genes. This information has tremendous application in agriculture, medicine, and environmental sciences (Montgomery et al. 1994; Morton 1955; Litt and Luty 1989; Klungland et al. 1995; Peters et al. 2003; Chial 2008).

Gene mapping methods are divided into (a) genetic mapping and (b) physical mapping.

A,B,C,D denotes location of genes on chromosome

**Gene Map, Fig. 1** A gene map showing position of genes A–D on chromosome

## Genetic Mapping

Before sequencing of human genome, mapping of gene was carried on the basis of gene transmission in pedigree analysis and distinct phenotypes associated with different alleles of same gene. The gene sequence data was not needed to assign chromosomal location to genes.

The important factors deciding gene location were – phenotype associated with gene and cosegregation of two genes. Two closely located genes had highest chances of cosegregation or linkage. The data obtained from recombination frequencies was used to determine exact distance between genes.

Even before genome information-based mapping, many genes had already been mapped on X-chromosome due to ease with which sex-linked traits could be determined through pedigree analyses. However, gene mapping on autosomes was quite a challenge as these contain non-sex-linked genes. To some extent pedigree analysis (generation analysis) helped to solve the purpose and researchers were able to generate linkage maps of the 22 human autosomes using linkage phenotypes in pedigrees. This remarkable landmark started with research published by Donahue et al. (1968) when the group successfully proved Duffy blood group locus, involved in imparting blood heterozygosity, to be located on chromosome 1 (Klungland et al. 1995). Locus is defined as position or coordinates of a gene on chromosome.

Other than chromosome linkage, gene maps can also be based on molecular or DNA techniques such as restriction fragment length polymorphisms (RFLP), random amplification of polymorphic DNA (RAPD), amplified fragment length polymorphism (AFLP), simple sequence repeat (SSR), and single nucleotide polymorphisms (SNP), which are most commonly used in genetic linkage analysis.

Recently, a comprehensive research resource Online Mendelian Inheritance in Man, OMIM<sup>®</sup> containing description of human genes and phenotypes and their relationship, is launched. OMIM is based on the published peer-reviewed biomedical literature and is used by

overlapping and diverse communities of researchers as well as students. OMIM.org has enhanced search capabilities such as genome coordinate searching and thesaurus-enhanced search term options (Amberger et al. 2015).

## Physical Mapping

Post genomic era has brought revolution in gene mapping techniques. The physical map representing a partial ordering of specific DNA sequences by their position on a chromosome is prepared to locate specific genes. There are several types of physical maps including cytological maps, restriction maps, STS content maps, radiation hybrid maps, ordered clone collections (i.e., “contig maps”), and the DNA sequence of an entire chromosome, constructed by a wide range of experimental methods without having any complete sequence information (Vaiman et al. 1996; Xiong et al. 1996; Reece 2000).

## Conclusion

Gene map describes the coordinates of gene on a chromosome. Gene maps offers a great scope of development and betterment for animals especially livestock and farm animals. With advent of more sophisticated techniques more information on gene location and the rationale will be revealed.

## Definition

The sum of all the genes in a given population at a given time can be referred to as **gene pool**. The term gene pool is used in reference to a population which includes all individuals of the same species and includes all genes and combinations of genes (sum of all the alleles) in the population.

## Introduction

The concept of gene pool was given by Russian geneticist Aleksandr Sergeevich Serebrovskii in the 1920s as *genofond* (gene fund). The term “*Genofond*” was imported to the United States from the Soviet Union by Theodosius Dobzhansky, who translated it into English as “gene pool.” Gene pool refers to the collection of genes in an interbreeding population that includes each gene at a certain frequency in relation to its alleles. The gene pool is a measure of generic diversity. The composition of a population’s gene pool can change over time through evolution. This can occur by a variety of mechanisms such as mutations leading to genetic variation, natural selection, genetic drift, habitat diversity, and geographical isolation. Such processes can cause an altered gene pool which is attenuated to the needs of the population’s specific environment. For example,

the migration of human population from equatorial region towards north where they were exposed to lesser amount of sunlight, resulted in variations in skin color over due course of time. The genetic modifications responsible for changes in the skin color become part of this population's gene pool. In contrast to this, several endemic species of tortoise and marine iguanas of Galapagos Island and aye-aye species of lemur in Madagascar island are example of least diverged genepool.

### Changes in the Gene Pool

Gene pool changes with time, it does not always stay the same. The changes in the gene pool of a population over time that result in changes to the varieties of individuals in a population is known as **microevolution**. Example of microevolution may include bacteria that have become insensitive to antibiotic over time. Small changes in the gene pool can happen for a number of reasons; a few of these have been listed below (Windows to the Universe 2011):

- **Gene Mutation:** Mutations are the source of new allele in gene pool. If a mutation occurs in the gamete producing cells and get fixed during meiosis, then when the gamete is fertilized, this mutation will enter gene pool. Any mutation that enters the gene pool is acted upon by natural selection. Alleles that result from unfavorable mutations are selected against and remain in the gene pool only if they are recessive, while favorable mutation can lead to speciation. Neutral or silent mutations are not acted upon by natural selection.
- **Gene Flow:** Gene flow refers to inflow of new traits by the migration of new individuals of the species into or out of certain geographic location that can affect gene pool. Gene pool can shrink due to loss of certain traits from a given population due to migration or natural selection. Gene pool can be enriched due to

immigration of diverged population into certain otherwise isolated locality.

- **Genetic Drift:** It is the change in the frequency of an existing gene variant (allele) in a population over years due to chance (sampling error), which can affect the gene pool. For example, if a few individuals leave a population and establish a new one, their gene pool may not have the same frequency of genes as in the population they left. Inbreeding of such population causes reduced genetic variation, thus causing a founder effect. Sometimes, catastrophic environmental events that reduce the population size and consequently causing loss of alleles in the population lead to reduction in genepool.
- **Natural Selection:** It is the key mechanism responsible for evolution. Some genetic differences are favored by nature and improve the chance of survival of individuals that have them. For example, hawks with large sharp talons may be more likely to survive than hawks with small talons. As the surviving alleles are preferred to be passed on to next generation, the genes for large talons are more likely to be passed on. Eventually the gene pool shifts towards large talons. Population with large and diverse gene pool have better survival fitness, while population with narrow gene pool have low fitness and under the pressure of natural selection, the species may become extinct.

When the changes in the gene pool of a population occur over a very long period of time, and the changes are large enough that the population is no longer able to breed with other population, such population is then considered as a different species. This process is known as **macroevolution**.

### How to Measure Gene Pool?

For measuring gene pool, it is very important to know how many variants of a gene are present in

the given population. The size of the gene pool is a direct measure of the genetic variation in a given population. Genetic variation is generally expressed as a relative frequency. Relative genotype frequency and relative allele frequency are the two most important measures of genetic variation. The distribution of genetic variation in a population can be known by relative genotype frequency. Relative allele frequency is the percentage of all copies of a certain gene in a population that carry a specific allele. This is an accurate measurement of the amount of genetic variation in a population.

This can be achieved by:

- Simply estimating relative phenotype frequency by calculating frequency of observable trait appearing in the population
- Calculating relative genotype/allele frequency in a population, which gives accurate estimation genetic variation in a population. Allele frequency can be calculated if there are two forms of alleles known for the genotype. The relative frequency can be mathematically expressed as:  $p^2 + 2pq + q^2$  (also known as Hardy-Weinberg equilibrium), where allele frequency remains unchanged in population.

However, when distinct forms of alleles are not obvious, genotyping can be performed by sampling DNA from individuals in the given population and using RFLP, microsatellite markers, or by DNA sequencing. Further, mitochondrial DNA markers are also used to identify different variants.

## Gene Pool Centers

Gene pool centers refer to areas on the earth where important crop plants and domestic animals originated. They have an extraordinary range of the wild counterparts of cultivated plant species and useful tropical plants. Gene pool centers also contain different subtropical and temperate region species. The major gene pool centers are as under:

1. Mediterranean
2. South American

3. South West and Middle East
4. African
5. South Mexican and Central American
6. Indian
7. Central Asian
8. East Asian

## Gene Pool Concept in Crop Breeding (My Agriculture Information Bank 2015)

Gene pool of a crop includes all cultivars, wild species, and wild relatives containing all the genes available for breeding. Based on degree of relationship, the gene pool of a crop can be divided into three groups (Harland and Dewet 1971),

1. Primary gene pool
2. Secondary gene pool
3. Tertiary gene pool

These are briefly discussed below:

### 1. Primary Gene Pool (GP1)

The gene pool in which intermating is easy and leads to production of fertile hybrids is known as primary gene pool. It includes plants of the same species or of closely related species which produce completely fertile offspring's. In such gene pool, genes can be exchanged between lines simply by making normal crosses. This is also known as gene pool one (GP1).

### 2. Secondary Gene Pool (GP2)

The genetic material that leads to partial fertility on crossing with GP1 is referred to as secondary gene pool. It includes plants that belong to related species. Such material can be crossed with primary gene pool, but usually the hybrids are sterile and some of the progeny to some extent are fertile. This type of gene pool is also known as gene pool two (GP2).

### 3. Tertiary Gene Pool (GP3)

The genetic material which leads to production of sterile hybrids on crossing with primary gene pool is termed as tertiary gene pool or gene pool three (GP3). Transfer of gene from such material to primary gene pool is possible with the help of special techniques.

## Conclusion

Gene pool represents total number of genes present within a population. Populations with larger gene pool tend to have more genes and hence show more genetic diversity. Each gene has a specific purpose such as giving plants or animals specific characteristics, resistance to disease, tolerance to harsh climate, etc. So, population with a larger genetic diversity will be better adapted to deal with disease outbreaks and harsh environmental conditions. On the other hand, populations with a lesser number of genes in their gene pools will be susceptible to such problems which may cause them to become endangered. Hence populations with a large gene pool are more likely to survive, while those with small gene pool are in danger of acquiring genetic diseases, infertility, deformities, etc. Gene pool gives an idea of the number of genes, the variety of genes, and the type of genes existing in a population. It can be used to help determine gene frequencies or the ratio between different types of genes in a population (Biology Online 2008).

## Gene Targeting

Hakima Flici

Centre for Chromosome Biology (CCB), School of Natural Sciences, National University of Ireland Galway, Galway, Ireland  
Regenerative Medicine Institute (REMEDI), National University of Ireland Galway, Galway, Ireland

## Definition

Gene targeting is the process of making specific changes to the DNA of a cell or an organism that can be permanent or conditional.

## Introduction

The ability to engineer biological systems holds immense potential for applications across basic science, medicine, and biotechnology. Gene targeting has been a powerful research tool for scientists that has gained and continues to gain valuable information about genetics and gene function by studying the effects of changes in DNA, by adding or removing either whole genes or single bases, or by manipulating the levels of gene expression. For a long time, geneticists used chemicals or radiation, such as ethyl methanesulfonate (EMS) and X-ray mutagenesis to cause DNA lesions (Lewis and Bacher 1968; Muller 1927). However, they had no way of controlling where in the genome the mutation would occur. By the development of new gene targeting strategies, such as the nuclease-based gene-targeting technologies (Gupta and Musunuru 2014), the potential today exists to accurately incorporate modified genetic material into the genome of several recipient organisms.

## General View

Gene targeting experiments allow for the modification of a selected DNA sequence within its

genomic locus, manipulations that can lead to gene inactivation by its complete deletion or by the creation of subtle mutations, the replacement of the gene by another gene or by any DNA sequence, or correction and creation of genetic mutations. In the best condition, the incorporated DNA fragment is accurately returned back to its homologous location in the genome and becomes inserted at the target locus; this is feasible through homologous recombination that depends on the ability to find and pair homologous DNA fragments between the target, endogenous chromosomal sequence, and the exogenous fragment, the donor. Homologous recombination is a natural process used by eukaryotic cells to repair harmful double-strand DNA breaks and to exchange nucleotide sequences between similar (homologous chromosome) or identical (sister chromatid) DNA molecules during meiosis (Sung and Klein 2006). Gene targeting can also concern the manipulation of gene expression at the mRNA level using oligonucleotides. Generally, this mechanism implicates the hybridization of the oligonucleotide fragment with the complementary mRNA sequence, followed by destruction of the hybrid by cellular enzymes.

Gene targeting led to a revolution in the ability to interrogate the function of specific genes, revealing the molecular basis of several biological phenomena from animal diversity to human pathologies. A large number of mutant cell lines and model organisms have been created to totally or partially inactivate the function of a selected gene to determine its role. A large number of human diseases result from genetic mutations that lead to the synthesis of defective proteins or to a deregulation of their expression and as a consequence can cause disturbances in fundamental molecular and cellular mechanisms. The conventional therapies are intended to treat the symptoms caused by those genetic defects. Gene therapy using gene-targeting strategies targets the origin of the pathology. This consists of incorporating a functional copy of the mutated gene, or another gene coding for a therapeutic activity, or repairing the mutation that is at the source of the physiological disorder. Therefore, gene targeting

represents an attractive genome-editing tool for not only gene function analysis but also for gene therapy applications.

## Gene Targeting Techniques

### Nuclease Systems

Several nuclease-based gene-targeting technologies have been developed (Gupta and Musunuru 2014). These technologies include zinc-finger nucleases (ZFNs) (Urnov et al. 2010), transcription-activator-like effector nucleases (TALENs) (Christian et al. 2010), and clustered regularly interspaced short palindromic repeats/CRISPR-associated sequence (CRISPR/Cas) system (Cong et al. 2013). ZNF is an artificial nuclease constructed by fusing a modular array of Cys2-His2 DNA-binding zinc fingers to the nuclease domain of the restriction enzyme *FokI* (Kim et al. 1996). This chimeric protein is usually composed of 3-6 zinc fingers that recognize three nucleotides each, providing DNA binding specificity to the nuclease. Since the *FokI* nuclease domain requires dimerization to work, a pair of ZFNs must be designed to induce the DNA cutting (Urnov et al. 2010). As ZFNs, TALENs were developed by fusing the *FokI* endonuclease domain with an array of TALE repeats. TALE proteins are major players during plant infection; they are secreted bacterial proteins that regulate the gene expression of the host cell by binding to specific DNA promoter regions (Christian et al. 2010). The CRISPR system functions as an adaptive immune system in bacteria and archaea that defends against phage infection (Mojica et al. 2005). In this system, an endonuclease is guided to specific genomic sequences by a single guide RNA (gRNA), resulting in DNA cutting near a protospacer adjacent motif (PAM) sequence. Those nucleases induce specific double-stranded breaks (DSBs) that stimulate the cellular DNA repair mechanisms by natural processes known as nonhomologous end joining (NHEJ), by directly rejoining the two DSB ends, and homologous recombination, a process that requires a repair DNA template (Haber 2000). NHEJ-mediated DSB repair can result in the

formation of small insertions or deletions into the coding sequence of a gene causing a frame shift in translation that leads to mRNA degradation or results in the production of a nonfunctional truncated protein. Homologous recombination occurs by using a DNA repair template with homology arms to replace a mutated gene directly and restore mutated gene function without modifying the regulation of gene expression. In addition, nuclease-based gene-targeting systems are being used for nongene-editing purposes such as activation and inhibition of gene expression, as well as for fluorescence tagging of chromosomal regions and individual mRNAs to track their cellular location (Bedell and Ekker 2015; Kaneko and Mashimo 2014).

### Cre-lox System

Cre-lox recombination is a sophisticated site-specific recombinase technology that allows DNA modification to be targeted to a specific cell type or to be triggered by a specific external stimulus. Cre is a recombinase protein derived from the P1 bacteriophage that catalyzes recombination between loxP sites (Sauer and Henderson 1988). LoxP sequences are formed by a consensus sequence with two palindromic sequences separated by a spacer region that is responsible for the sequences orientation. A DNA fragment with flanking loxP sites will be excised by homologous recombination in the presence of Cre, leaving a single loxP site making the point of excision and re-ligation of upstream and downstream DNA. Because the loxP sites are relatively small and placed in intronic regions, they do not typically interfere with normal gene transcription. The most important aspect of Cre-lox is its reversibility; a transgene can be inserted, expressed, studied for cellular effects, and then removed. This is possible with the modified version of Cre, Cre-ERT2, a chimeric protein that translocates to the nucleus in the presence of tamoxifen. Therefore, regardless of ubiquitous or cell type-specific expression of Cre-ERT2, the Cre-mediated recombination will only occur after tamoxifen treatment, providing sophisticated timing control capabilities.

### Viral-Based Systems

Adeno-associated virus (AAV) is a single-stranded DNA animal virus. The wild-type genome contains two open reading frames (ORFs) termed *rep* and *cap*, which encode non-structural and structural proteins, respectively. In addition to their broad potential for therapeutic gene delivery, recombinant AAV (rAAV) vectors possess the innate ability to stimulate homologous recombination in mammalian cells at high efficiencies (Ellis and Bernstein 1989). By altering the DNA sequence between the AAV homology arms, a broad range of modifications can be introduced in a targeted manner by natural recombination with the target locus, including single-base substitution (Inoue et al. 1999; Inoue et al. 2001), and site-specific integration (Hirata et al. 2002). rAAV can transduce various cell types in different species, and several studies have reported the successful application of rAAV vectors in different model organisms including mouse, rat, monkey, and other (Flierl et al. 2005).

### Oligonucleotides

The usage of oligonucleotides in gene targeting is used in the antisense field for many years to block gene expression at the mRNA level. Antisense oligonucleotide agents induce the inhibition of target gene expression in a sequence-specific manner by exploiting the ability of oligonucleotides to bind to target RNAs via Watson-Crick hybridization. Once bound, the antisense agent either disables or induces the degradation of the target RNA. There are three major categories of gene-silencing molecules: (1) antisense oligonucleotide derivatives that, depending on their type, recruit RNase H to cleave the target mRNA or inhibit translation by steric hindrance; (2) ribozymes and deoxyribozymes catalytically active oligonucleotides that cause RNA cleavage; and (3) small interfering double-stranded RNA molecules that induce RNA degradation through a natural gene-silencing pathway called RNA interference (RNAi). Specialized oligonucleotides capable of forming a third strand of the helix to block gene expression, single-stranded oligos to introduce and adduct at a specific site were also described (Haber 2000).

## Conclusion

The sequencing of human and different model organism genomes with the continuous development and performance of gene targeting techniques should be associated with a great expansion of functional genomics. Gene targeting techniques will allow the total or partial inactivation of protein function in order to determine their role or their labeling for in vivo analyses. The techniques that are used to disrupt or to restore gene function also have potential for therapeutic applications. However, considerable advances in the comprehension of their mechanisms, particularly those involved in the downstream response to the induced damage, are needed before these approaches move from bench to bedside.

## Definition

*Genes* are defined as the fundamental physical and functional units of heredity. They serve as the carriers of genetic information from parents to offspring across generations.

## Main Text

### Genes Are Inheritable Genetic Units

The existence of inheritable genetic units was first described by Gregor Mendel as early as 1865 and the term “genetics” was first used in 1905 by William Bateson (Keynes and Cox 2008). Genes are made up of DNA (deoxyribonucleic acid), positioned on chromosomes and code for proteins. The chromosomes comprised of autosomes and sex-linked chromosomes in entirety are known as DNA that constitutes the genetic material. Genes are made up of introns, exons, and 5' and 3' untranslated regions. Exons are the regions that code for the corresponding protein and introns are the noncoding parts that are removed during the process of mRNA splicing (Fig. 1).

Two or more alternative forms of a gene located at the same chromosomal position are known as *allele*. The position at which a gene is placed on the chromosome is often referred to as *locus*. Majority of the multicellular organisms including humans are diploid, containing a pair of each chromosome or homologous chromosomes. Thereby, every allele of a gene on a single

chromosome has its allele pair at the same locus of the homologous chromosome. The two alleles of a gene are inherited from each parent. These alleles can vary from each other if they contain mutations. Such genes made up of two different alleles are known as *heterozygous* with respect to that gene. Condition in which both the alleles are same makes that gene *homozygous*.

### Genetic Expression

Genetic information on the DNA is converted into RNA (ribonucleic acid) also known as messenger RNA (mRNA) by a process called *transcription*. This in turn gets decoded by ribosomes into the respective protein by a process called *translation*. Nucleotides are the building blocks of DNA and RNA (ribonucleic acid). Each nucleotide is composed of a nitrogenous base, a five-carbon sugar (ribose or deoxyribose) and a phosphate group. Four nitrogenous bases, adenine (A), guanine (G), thymine (T), and cytosine (C) make up the nucleotides in the DNA. Thymine is replaced by uracil (U) in mRNA. Genes therefore are constituted of nucleotides that appear similar to any other region of the genome. However, they are equipped with a feature that distinguishes them from rest of the DNA. This is the sequence specific promoter region that precedes a gene. Promoters facilitate the binding of RNA polymerase to initiate transcription. The information content on genes is read from the corresponding mRNA as a set of rules called the *genetic code*. Every triplet of nucleotide sequences known as the *codon* specifies for a single amino acid. Only 20 amino acids appear in the genetic code, a combination of which makes up all the known proteins in any living organism. The initiation codon “AUG” encodes methionine as the first amino acid in eukaryotes and a modified methionine (fMet) in prokaryotes. Some proteins of the mammalian cells, however, can also initiate translation with leucine decoded from “CUG.” Certain viruses contain RNA as the genetic material instead of DNA. They use reverse transcription by an enzyme reverse transcriptase to synthesize DNA from the RNA prior to protein synthesis.

**Genes, Fig. 1 Structure of a gene.** Gene structure representing the 5' and 3' UTRs; exons E1, E2, E3, E4; and the intervening introns I1, I2, I3. The gene gets transcribed into pre-mRNA. Splicing removes the introns and

generates the mature mRNA with a 5'cap at the 5'UTR and poly-A tail in the 3'UTR. This mRNA gets translated into the corresponding protein coded by the gene

### Inheritance of Genetic Information

Animal cells contain two types of DNA, nuclear and mitochondrial. Plant cells additionally contain chloroplast DNA. Each mitochondrion can contain 2–10 copies of the DNA and mitochondrial proteins can be coded by nuclear genes too. The human mitochondrial DNA (mtDNA) is made up of 37 genes and along with most other species is inherited exclusively from the mother. Nuclear DNA inheritance is however seemingly different. *Meiosis* of germ cells is a specialized cell division process that reduces the chromosome number ( $2n$ , representing the DNA that contains a pair of each chromosome) to half and produces four haploid cells or gametes ( $n$ ). During the process of meiosis, the homologous chromosomes pair with each other and undergo crossovers leading to *genetic recombination* that produces four gametes with unique genetic content different from the parent cell. Genetic recombination is an event that exchanges genetic information randomly between two homologous chromosomes to produce chromosomes with a new

combination of genetic information. Upon fertilization, two gametes fuse and create a diploid cell with paired chromosomes. This process results in the inheritance of genetic information from the parents that is exclusive and determined by the randomness of genetic recombination event. The genetic information is embedded in the genes. This produces individuals that can decode distinctive genetic material which makes them unique from any other individual. The human genome contains ~25,000 genes (Van Straalen and Roelofs 2006). This is a small number as compared to much simpler eukaryotes like yeast that contains 6000 genes, fruit fly made up of 14,000 genes, or *Caenorhabditis elegans* which contains 18,000 genes (Van Straalen and Roelofs 2006). However, the biological complexity of humans has been advocated to a combinatorial diversity generated at the level of *post-translational modifications of proteins* (such as methylation, acetylation, glycosylation, phosphorylation to name a few).

Certain genes follow *Mendelian inheritance* where a specific trait is determined by a single

**Genes, Fig. 2** A homologous chromosome pair representing alleles (A, a) of a gene. Alleles A and a are inherited from each parent

gene. The phenotype (observable physical and behavioral features) is determined by the genotype (the allelic combination of a gene). Mendelian inheritance underlies several genetic disorders. Alleles that determine these traits can be dominant or recessive. Dominant alleles (A) express the corresponding phenotype when paired with the same or any other allele of the same trait, i.e., in homozygous or heterozygous states (AA or Aa). Recessive alleles (a) express the respective phenotype only when paired with a same allele (aa), i.e., in a homozygous combination. With knowledge of the genotype and corresponding phenotype, the dominant allele can be easily detected (Fig. 2).

### Genes and Disorders

Depending on the chromosomes on which the genes are located and if the causative alleles are dominant or recessive, Mendelian inherited genetic disorders can be autosomal dominant, autosomal recessive, X-linked dominant, X-linked recessive, Y-linked or of mitochondrial inheritance. Genetic disorders can also result from de novo mutations that arise independently. De novo mutations usually result in severe disorders that can result in a disrupted reproductive capacity or early death and hence never get inherited. Several genetic disorders also result from polygenic contribution of more than one gene and do not follow a Mendelian inheritance. However, knowledge of the causative genes in any genetic disorders is helpful to lead to the correct research that can be used to treat these disorders. Gene therapy has been an area of great interest for several years to treat genetic disorders and only recently success has been made in this field in patients with beta thalassemia, hemophilia, and hereditary blindness.

## Definition

Genetic code is the set of instructions in the form of linear sequences of nucleotides encoded on DNA and subsequently on mRNA in the form of triplets of nucleotides, the codons, which correspond to 20 different types of amino acids in proteins in living cells.

## Introduction

While a codon is a triplet of nucleotides, the genetic code refers to the correct sequence of the

codons which results in corresponding amino acid sequence of a protein. Each codon in the genetic code consists of three nucleotide bases arranged in a specific order, with each combination corresponding to a specific amino acid. The genetic code can be expressed as either RNA codons or DNA codons, which in living cells is translated into proteins. Translation is accomplished by **ribosome** subunits, which links amino acids in an order directed by mRNA sequences, via transfer RNA (tRNA) molecules that transport amino acids corresponding to codons and help in decoding of the genetic code into corresponding proteins. Many organisms use standard genetic code with few exceptions which include some bacteria, some single-cell eukaryotes, and mitochondria that use nonstandard code.

## Discovery

After the discovery of structure of DNA in 1953, efforts to understand how proteins are encoded in genetic material DNA began. George Gamow attempted to solve the problem of how the combination of four bases (adenine, cytosine, thymine, and guanine) in nucleotide chain directs the synthesis of proteins from amino acids. He postulated that sets of three bases must be involved to encode the 20 standard amino acids to make proteins, which would allow a maximum of  $4^3 = 64$  amino acids.

With the help of genetic studies, Crick, Barnett, Brenner, and Watts-Tobin in 1961 showed that the code is a triplet code which was later confirmed by biochemical studies. Although base compositions of codons were determined, the order of bases within the codons was still unknown. It was Marshall Nirenberg and Heinrich J. Matthaei who first determined the sequence of the codon in cell-free extract of *E. coli*. By then, base composition of 50 codons was assigned to the amino acids, but trinucleotide synthesis was still a major problem. Har Gobind Khorana and his associates after series of studies over many years were able to synthesize oligo and polynucleotides using chemical method. At that time only 20–30 trinucleotides were synthesized.

Khorana and his colleagues were able to synthesize 64 trinucleotides by chemical method. Then in 1965, Robert Holley from Cornell University deciphered the structure of transfer RNA (tRNA), an adapter molecule which carries specific amino acids corresponding to codon on mRNA template to ribosomal assembly during translation process.

Marshall Warren Nirenberg, Har Gobind Khorana, and Robert William Holley were awarded the Nobel Prize in Medicine in 1968 for deciphering the genetic code and its importance in protein synthesis (Fig. 1).

## Characteristics of Genetic Code

Here are mentioned some features of the genetic code (as described by F H C Crick in his article “The Origin of the Genetic Code” published in 1968) which are of such a general type that they do not depend upon the details of the code at all.

1. Each codon comprises triplet of bases.
2. Some codons function special codons like AUG as start codon which codes for methionine (Met), and UAA, UAG, and UGA are called termination codons or stop codons or nonsense codons which do not code for any amino acid.
3. The genetic code is universal (except mitochondria where AUA codes for methionine and UGA for tryptophan instead of isoleucine and stop codon, respectively, some bacteria and few single-cell eukaryotes) i.e., codons that code for specific amino acids are identical in nearly all species. To prove this, two hypotheses have been proposed.

- *The stereochemical theory*: According to this theory genetic code is universal because of its stereochemical reasons, i.e., high affinity between an amino acid and its corresponding codon or anticodon.
- *The frozen accident theory*: This theory stated that allocation of codons to amino acids was merely a matter of chance. Assuming that all

**Genetic Code, Fig. 2** Schematic diagram showing that the genetic code is read in open reading frame in non-overlapping manner

**Genetic Code, Fig. 3** Schematic diagram showing that the genetic code can be read in three different possible reading frames

- organisms evolved from a single ancestor and inherited the same set of codons so they do not change and any change in the codon would be highly disadvantageous or even lethal in extreme form.
4. Most interesting feature of genetic code is its degeneracy means a single amino acid may be coded by more than one codon but one codon specifies only one amino acid.
5. Codons are read in open reading frame (ORF) and non-overlapping manner (Fig. 2).
6. Every coding sequence has three possible reading frames (Fig. 3).
7. There is no punctuation between consecutive codons, i.e., they are comma-less.

## Nonstandard Amino Acids

In general all organisms have proteins composed of 20 amino acid encoded by 61 standard codons. However, there are the cases (certain archaea, eubacteria, and eukaryotes) where amino acid in the protein is not one of the standard amino acids, i.e., selenocysteine (21st amino acid) and pyrrolysine (22nd amino acid). These two amino acids are called nonstandard amino acids and are substituted for standard stop codons, UGA that code for selenocysteine and UAG for pyrrolysine depending on signal sequences on mRNA. Here it is interesting to know that UGA is still used as a termination codon or stop codon, but the translation machinery is able to discriminate when to use UGA as stop codon and when to code for selenocysteine. However, the mechanism is still not known.

## Definition

In the process of sexual selection to produce better-fitted offspring, the parental genetic combination arises the issue of compatibility because the closely related individuals along with interspecies mating provide lower fitness and even sterility of the offspring due to interaction of the genetic elements.

## Introduction

It is the basic characteristic feature of an animal to reproduce and propagate its genetic material to the next generation. In this process, selection of partner on the basis of their genetic makeup is an important feature. Up to what extent partners are biocompatible or genetically compatible is the question female faces during choosing of good genes. The model of genetic incompatibility was proposed by Dobzhansky (1936) and Muller (1942), and they found that independent evolution of two populations can generate alleles compatible in native background whereas deleterious on genetic background of other population rendering hybrid inviability or sterility. Genetic compatibility is one of the most important parameters of evolution based on which mate choice, polyandry, and extra-pair copulation also come into the scenario. Genetic histocompatibility in the form of major histocompatibility complex (MHC)

plays a significant role in the partner selection and less parasitized better-fitted offspring.

### Dilemma Between Genetic Compatibility and Genetic Dissimilarity

Selection of good genes (genetic dissimilarity) for better fitness of the offspring (genetic compatibility) put the female in dilemma. To derive the relationship between genetic dissimilarity and genetic compatibility, it has been found that highest level of fitness (genetic compatibility) achieved at intermediate level of genetic dissimilarity (Bateson 1983). Inbreeding or mating with close relative (low genetic dissimilarity) provides lower fitness (genetic compatibility) to the offspring, and even mating with different species also causes genetic incompatibility like hybrid vigor and hybrid sterility (hybrid incompatibility). Genetic compatibility furnishes as a nonadditive genetic variance (interaction between genetic elements) in fitness, whereas good gene acts as an additive genetic variance in the fitness (Neff and Pitcher 2005). Females are in dilemma of choosing good genes or compatible genes during sexual selection. The females administer both the parameters to avoid confrontation and provide optimum survival and fitness to the offspring.

### Ways to Achieve Genetic Compatibility

The intriguing puzzle in sexual mode is to avoid genetic mismatch or incompatibility and selection of partner which will provide higher fitness to the offspring. Parasite avoidance is one of the ways to get away from the genetic incompatibility, since there are many evidences like selection of mate which is healthy, parasite-free reduces parasite load, and also the less parasitized individuals have higher reproductive success. In support to this, the red queen hypothesis presumes that the new gene combination provides the platform to combat with currently dominating parasite.

During mate selection, male confronts with three demands of female, viz., (a) there is enormous variation of resistance gene in population,

(b) she knows about her immune genes, and (c) she can recognize immune gene of potential mate and choose accordingly.

For reproductive success, male ornamentation is one of the promising features of sexual selection, e.g., spur length of pheasants (*Phasianus colchicus*) which is correlated with male survival, offspring fitness, and sexual attractivity (Von Schantz et al. 1996). This spur length is also correlated with MHC (major histocompatibility complex) genotype, and the female can discriminate the MHC from the spur length of the male.

In the year 1974, Zinkernagel and Doherty explain the role of MHC in recognition and processing of foreign antigen followed by Gorer who discovers the mice MHC complex known as H-2 complex. Due to codominant expression of MHC alleles, MHC heterozygous is advantageous possessing greater resistance against different pathogens by presenting a greater variety of peptides to the T-cell receptor.

### Genetic Incompatibility Hypothesis

According to this hypothesis, the quality of an offspring depends on the interaction between paternal and maternal genes, i.e., the haplotype of each partner matters. The incompatibility may rise due to three components: homozygote disadvantage, selfish genetic elements, and coadapted gene complexes (Nordeide 2007).

### Homozygote Disadvantage

Genomic incompatibilities are theoretically because of two reasons:

- (a) Dominance – Heterozygous experiences lower expression of recessive deleterious mutations because heterozygous can bind twice as many foreign peptides as homozygotes (homozygote disadvantage) (Hughes and Nei 1992) and balances the costs of numerous MHC allele expression.
- (b) Overdominance – Certain heterozygotes are superior, produce a greater variety of gene

products, favor parasite avoidance, and decrease the risk of autoimmunity (Penn and Potts 1999).

## Coadapted Gene Complex and Genetic Compatibility

### (i) Between species

Preferences for conspecific partner are universal to all animals. In reproductive character displacement, many examples about mating with wrong species (divergence) (Butlin 1989) have been reported. Lower fitness individuals are produced in mating between species because of (a) major differences in the genetic system of two groups (chromosome structure, number, etc.) which may interrupt meiosis and result in hybrid sterility, and (b) different genomic elements are coadapted differently, and the phenotypes suffer when they mixed together (Dobzhansky 1948).

Coadapted gene complex – It is a group of traits which if present together helps to enhance the individual fitness, whereas fitness will be compromised if they don't. This coadaptation is in the form of external or internal. Externally, phenotypical adaptation is with the environment and internally compatibility of new allele with the other alleles. For example, in the case of *Heliconius erato*, hybrid butterflies are fully viable and fertile, but they are prone to predators for their extreme coloration (Mallet 1993) (external coadaptation disadvantage). Internal coadaptation may also cause hybrid disadvantage even under standard condition, e.g., if parthenogenetic strain *Drosophila mercatorum* mates, the offspring shows hybrid viability disadvantages (Templeton et al. 1976) due to interaction between alleles of unlinked gene, chromosome, and chromosome arms.

### (ii) Between population within species

At any given set of loci, recombination will prevent retention of more than one coadapted gene complex in spite of less limitation in gene exchange within species breeding. Spatial or temporal subdivision between species creates

geographical population within species. Cross population mating reduces hybrid fitness and hybrid disadvantage due to breakdown of association between genes. Due to outbreeding, in few convincing cases, assortative mating driven by selection against genetic incompatibility has been reported (Butlin and Tregenza 1997). The fact about sympatric speciation driven by mate choice for genetic compatibility is confusing. Female selection for a particular male genotype like sperm protein binding is very common in the case of *Echinometra*, where intraspecific sperm protein binding variation has been found.

### (iii) Within population

Contributing factor for the optimal balance between inbreeding and outbreeding is coadaptation gene complex. Recombination suppression is the criteria to evolve and maintain coadaptation. Further if these coadapted regions are protected from recombination, females will not exercise mate choice to maintain the coadapted gene complex and will not be a common source of variation in genetic compatibility. Ratti et al. (1995) found that in pied flycatchers (*Ficedula hypoleuca*), breeding with low genetic similarity birds has more offspring and suggests that females may be engaged in extra-pair copulation to reduce the unspecified cost of fitness.

## Selfish Genetic Elements and Genetic Compatibility

Genomic conflict or genetic incompatibility within all organisms arises because of selfish genetic elements like segregation distorters, transposable elements, inherited bacterial symbionts, autonomous replicating elements, converting elements, transmitting sex-enhancing elements, t-complex in mice, etc. In two specific rules, it determines the sexual selection and genetic compatibility. Firstly the diversity of selfish genetic elements is correlated with the outbreeding rate of that species. Secondly the phenotype is often shown in hybrids but is not observed in within-population crosses (Hurst

and Werren 2001). In spite of cost bearing by selfish genetic element, its transmission provides advantages to the individual by helping to combat with the new mutation and also with the deleterious mutation.

Different species are sensitive to different meiotic drivers which are considered as selfish elements. Mate selection depends on this sensitivity to avoid creation of genetic compatibility in the offspring. Selfish genetic elements include selfish DNA and cytoplasmic symbionts or parasites and promote their transmission in the expense of affecting other genes, e.g., female stalk-eyed flies prefer X-linked suppressor containing males (Wilkinson et al. 1998) or males who lack meiotic drivers altogether (Lande and Wilkinson 1999). In case of parasitoid wasps *Nasonia vitripennis*, sperm, which lack meiotic drive B chromosome, will fertilize the egg in competition of other driver male sperm (post-copulatory choice) (Beukeboom 1994). In some cases, selfish genetic element encourages polyandry (Martin 2009).

## Conclusion

In the course of evolution, choice of sexual mode over asexual mode provides variation to the offspring with higher viability and reproductive success. Second level of reproductive success and increasing fitness of the offspring is the selection of partner where heterozygous provides advantage. Genomic compatibility in regard with selfish genetic elements and coadaptation gene complex drive the mate choice for better fitness of the offspring. To find a good gene, mate selection depends on genotype variation, and the discrimination is based on odor which is related with MHC. Heterozygous MHC haplotype provide better fitness and immunity to the animal and also reduce the risk of fetal abortion as found in homozygous parents.

## Genetic Drift

Neelabh

Department of Biotechnology, SR Institute of Management and Technology, Lucknow, Uttar Pradesh, India

Department of Zoology (MMV), Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

Random sampling of the organisms in a population leads to changes in the allelic frequencies. This process is termed genetic drift or allelic drift or the Sewall Wright effect (Goodhart 1963; Fisher and Ford 1950). The source of the change in frequency in case of genetic drift is just “chance.” In other words, unlike natural selection, no environmental factors influence the genetic drift to occur. Genetic drift is one of the basic mechanisms of evolution along with natural selection, migration, and mutation.

Another important feature related to genetic drift is that it is more evident in smaller populations. The reason behind this is that, in small populations, alleles that are present in lower frequencies face a greater chance of being lost than that of higher frequency alleles. Therefore, if the force of the genetic drift is strong

enough, it might result in a complete removal of those alleles, leading to a loss in the genetic diversity of the population.

Population bottlenecks and the founder effect are the favorable conditions for the occurrence of the genetic drift as they can drastically reduce population size, which is an important factor for the activity of genetic drift. The bottleneck effect can be caused by a natural event like a natural disaster that wipes out most of a large population. This results in the genetic structure of the survivors becoming the genetic basis for the entire population, which may be very different from the population before the disaster. For example, in the case of *Phytophthora infestans*, the cause of potato blight, a single clone that escaped out of Mexico and into North America resulted in the Irish potato famine and then was circulated globally (Goodwin et al. 1994). Similarly, the present population of the North American bison has resulted from a bottleneck which constricted the original population to less than a hundred (Hedrick 2009).

Another extreme example of genetic drift is the founder effect. This effect occurs when a small group of individuals separates from the large population to establish a colony. The small group of individuals might not represent the entire previous population or the alleles present might be in a different frequency than the original population (Peltonen 2001). According to Milgroom et al. (1996), the population of chestnut blight (*Cryphonectria parasitica*) in North America also shows some characteristics of a founder population due to much reduced genetic variance from the original population in Asia. The most important difference between the bottleneck effect and the founder effect is that the former involves catastrophe while the latter involves colonization.

Genetic drift is also termed as random drift because the change in the allelic frequencies occurs merely by chance and is not predetermined. The consequences of the genetic drift include the increase in inbreeding coefficients and also homozygosity in a population. The populations that regularly undergo extinction and recolonization are more susceptible to genetic drift.

## Genetic Fallacy

Muneeb A. Faiq  
 Dr. Rajendra Prasad Centre for Ophthalmic Sciences, All India Institute of Medical Sciences (AIIMS), New Delhi, India  
 Neuroimaging and Visual Science Laboratory, Langone Medical Centre, New York University School of Medicine, New York, NY, USA

## Synonyms

[Fallacy of origins](#); [Fallacy of virtue](#); [Heritability fallacy \(in behavioral genetics\)](#)

## Definition

It is the practice of basing the veracity of a claim on the origins, history, genes, etc., that may be

completely irrelevant to the point in question. In the context of the science of genetics and molecular biology, it may be defined as attributing a behavioral trait to genes without any respect to the environment.

## Description

“Genetic fallacy” may refer to a line of arguments or justification/s invoking genetics that seem to be logical but are illogical, and out of context thereby erroneously attributing an observed trait or phenomenon to irrelevant causes (like origins and genes). Genetic fallacy has many synonymous connotations like “Fallacy of origins,” “Fallacy of virtue,” and cover arguments that come under the arguments of irrelevance where the conclusions about the observed phenomenon (or a behavioral trait) are based on something’s/someone’s origin, history, background, genetics, with no relevance to the actual meaning and context. The act Genetic fallacy may or may not be a biased exercise, but it always denies to evaluate a trait on the basis of merit. The origin of the term goes back to the philosophers Morris Raphael Cohen and Ernest Nagel who coined the term in 1934 in their book *Logic and Scientific Method* (Honderich 1995). A coherent argument is (and should be) based on the premise having a direct bearing on the truth or falsehood of the claim; and there should be a direct relationship between the claim and the truth/falsehood of the argument (Damer 1980). But claiming genetic basis as the solo reason for a trait (particularly behavioral trait) without consideration the context (environment) is fallacious and misleading. Conclusions drawn by such an approach are disingenuous and often wrong. The structure of a typical genetic fallacy is based on a combination of two statements. The first statement/argument is “invoking the genesis” and the second statement is a “therefore statement.” It may be born in mind that these two statements don’t have any direct relationship with each other yet in a Genetic fallacy they are speciously thought to be related. The following is how the Genetic fallacy looks like:

Statement 1: The genesis/origin of the claim is put forth.

Statement 2: Based on just an apparent “therefore,” the claim is categorized as true or false.

An example of genetic fallacy is: “His father was wealthy, therefore, he is genetically predisposed to success in business.” Anyone’s success in business does not have any direct relation to one’s father’s economic status. Children of wealthy people are not all successful businessmen neither are the children of poor people business failures. Furthermore, genetic predisposition cannot be attributed as a cause of someone’s success in business. Upbringing, value system, education, skill set, development, belief system, circumstances, opportunities and many other reasons (collectively called environment) have a bearing on a person’s success in business. Attributing it solely to somebody’s genetics qualifies for being genetic fallacy.

Genetic fallacy is a philosophical term with little connotation to behavioral genetics. But a lot of use can be made of this phenomenon in genetics because behavior is a complex combination of genetics and environment. The interaction of these components is extremely intricate and genes are not the sole players in such a context. A person’s success may be attributed to many factors like intelligence, opportunity, hardwork, training, socioeconomic status etc., and a person becoming a successful businessman cannot just be attributed to the genetics.

Since Genetic fallacy is a philosophical term, a relevant term in science of behavioral genetics and molecular biology may be the “Heritability fallacy.” (Moore and Shenk 2017). According to Moore and Shenk, this term is one of the most misleading terms in behavioral genetics. They argue that the measurability of a particular trait is not an indication of “genetic heritability” of that trait. It is not indicative of the cause and mechanism of development of the trait. Also, it is not explanatory about the relative role and nature of interaction between genes and environment in shaping a behavioral trait of an individual.

A behavioral trait is an outcome of a complex combination of genetic, epigenetic and environmental factors which range from as objective

parameters as DNA sequence to as subjective factors as belief system and value system. There seem to be two distinct paradigms (viz. Genetics and Environment) interacting through an inter-phase (epigenetics) that results in development of a particular trait in a certain way. It is, therefore, important to emphasize that genetics has a role to play and environment also does have but the mechanism and extent of contribution of each paradigm is complex and we are just beginning to unravel the mysteries.

### Synonyms

[Gene polymorphism](#); [Mutations](#)

### Definition

Genetic variation (GV) is defined as the subtle genomic differences among individuals within or between populations that makes each or a group of organisms different from others.

### Introduction

Variations are found throughout the genome of an organism. However, these variations are not evenly

distributed. Instead, some regions are “hot spots” of variability like CpG islands, and some other parts are stable enough that don’t show variation (Mugal and Ellegren 2011; Xia et al. 2012) at all among the individuals. Variation in the genetic material of an organism is depicted in its phenotype. Almost every trait of an individual is affected by genetic variation. Variations in the eye color and hair color, ear lobes, height etc. are due to the genetic differences between individuals.

## Genetic Variation Drives Evolution

Genetic variation is an important evolutionary force as it provides the diversity within and between populations. Genetic variability makes an organism more adapted to its environment. Variations result in different forms of a gene (called alleles). For example, if a gene “A” is mutated to “a” and if the new allele (a) has some selective advantage for the individual either through fitness or fecundity, then the mutated allele will be transmitted to the next generation over a period of time. On the other hand, if the new allele is deleterious, then it would be selectively eliminated as the offspring carrying it will not survive. Preexisting advantageous mutations when selected will result in observation of new phenotypes. This process is called natural selection (Darwin 1859). Natural selection brings about changes in the gene frequency. Over few generations, this would result in speciation. Hence, disturbance in genetic equilibrium or Hardy-Weinberg equilibrium, i.e., change of frequency of alleles in a population would lead to evolution.

## Sources of Genetic Variation

Mutations, gene flow, and sexual reproduction are three primary sources of genetic variation.

### Mutations

Mutation is a process which produces altered DNA sequence. It may be induced by radiations and chemical mutagens in the environment or

insult from endogenous reactive oxygen species (ROS) or occur spontaneously due to endogenous factors (errors in chromosomal segregation, recombination, DNA replication and repair, and also spontaneous chemical damage to DNA). Mutations are inexorable. They may have adverse effects on organism's health and survival. Sometimes, they may have no obvious effects, or rarely, they may be beneficial for the bearer.

### Gene Flow

Gene flow is the transfer of genes from one population to another and thus affects the allele frequency. The rate of gene flow is directly proportional to the mobility of an individual and is limited by geographical barriers which may be natural or man-made. Cross-species hybridization in plants to generate new and improved varieties and gene transfer from bacteria or virus to new hosts lead to genomic variations.

### Sexual Reproduction

Somatic cells divide and multiply by mitosis that produces daughter cells, identical to the parent cell, whereas during gamete formation, a special type of cell division, i.e., meiosis, results in newer combinations of parental genotypes by crossing over and independent assortment of homologous chromosomes thus generating unique genotypes, followed by random fertilization. Sexually reproducing organisms are more diverse than the asexually reproducing ones.

## Types of Genetic Variants

Genetic variations are basically of three types, viz., single-nucleotide variations, insertion/deletions (indels), and structural variations. These variations may be rare or common depending upon their frequency in population and pathogenic or nonpathogenic.

### Single-Nucleotide Variations (SNV)

SNVs are the most common type of all variations where a nucleotide is replaced by another. It may be either transition (purine to purine or pyrimidine to pyrimidine) or transversion (purine to

pyrimidine or vice versa). When a SNV is common in a population or we can say its frequency is  $\geq 1\%$ , then it is known as single-nucleotide polymorphism (SNP). SNPs may fall within the coding or noncoding region of genes or in the intergenic regions. Coding region SNPs may be either synonymous (no change in amino acid) or non-synonymous (change in amino acid). SNPs are usually selectively neutral, but they often make an individual predispose to certain disease, e.g., SNPs in *MTHFR* (methylene tetra hydro folate reductase) predispose an individual to cardiovascular disease (Kluijtmans et al. 1996), cancer (Izmirli 2013), and neural tube defects (Botto and Yang 2000). SNPs also confer a selective advantage to individuals harboring them, e.g., Duffy blood group allele, FY(a-b-) (Duffy null phenotype), protects against malaria (Carvalho and Carvalho 2011). SNPs are cataloged in a public database, dbSNP (<http://www.ncbi.nlm.nih.gov/projects/SNP>). Coding region SNVs may affect the structural and functional aspect of a protein. They are usually deleterious and present less frequently in population ( $\leq 1\%$ ). They are known as rare variants. Rare variants which are clinically significant are cataloged in clinical variation database, ClinVar (<https://www.ncbi.nlm.nih.gov/clinvar>). SNPs present in non-coding regions are also reported to influence gene splicing and transcription factor binding. The functional effect of variants on the protein's structure and function can be predicted using in silico tools like SIFT, PolyPhen2, MutationTaster, etc. (Table 1).

### Insertions and Deletions (Indels)

Indels refer to DNA mutations involving insertion and deletion of one or more base pairs. These can have devastating effects on the gene because either translation of the gene is frame shifted or amino acids are deleted. For example, 3 bp deletion ( $\Delta F508$ ) in coding region of *CFTR* (cystic fibrosis transmembrane conductance regulator) gene is the most common cause of cystic fibrosis (Cutting 2015). However, nonpathogenic indel are often useful in mapping common ancestry in kinship and human origin studies because chances of two mutations of the same length occurring in the same genomic position are negligible.

## Structural Variations

Structural variation refers to large-scale structural differences in the DNA, originated mainly due to chromosomal rearrangements – deletion, duplication, novel sequence insertion, or inversion. They include copy number variations, variable number of tandem repeats, and chromosomal rearrangement.

## Copy Number Variations (CNV)

A CNV can be simple in structure, such as tandem duplication, or may involve complex gain and loss of homologous sequences at multiple sites in the genome. CNVs are genomic structural variants in which the number of copies of a particular segment is different in two or more different genomes as compared to a reference genome.

## Variable Number of Tandem Repeats (VNTRs)

These variations involve changes in the number of repeated DNA sequences arranged in tandem arrays. These are highly heterogeneous groups of loci. These are multiallelic markers while SNPs are generally biallelic. They are classified according to the size and number of their repeat units. They are sometimes considered as neutral markers. But there are many instances among various classes of VNTRs which shows phenotypic effects. VNTRs can be microsatellite, minisatellite, satellite, or telomere-repeat arrays.

## Microsatellites

They are also known as “short tandem repeats” (STRs) or “simple sequence repeats” (SSRs) having 1–6 bp long repeat units. Their copy number varies from 10 to 30. Microsatellites with some specific repeat units show clustering, but most are distributed throughout the genome which is useful in linkage analysis. The most common microsatellite is (CA)<sub>n</sub> repeat. Mutation at these regions may involve either increase or decrease in repeat units. Microsatellites are reported to be associated with many human diseases like fragile X syndrome (FMR1/FMR2;(CA)<sub>n</sub> repeat) and Huntington’s disease (HD; (CAG)<sub>n</sub> repeat).

## Minisatellites

Minisatellites are tandem arrays of repeat unit around 8–100 bp with a copy number of 5–>1000. They are generally GC rich. They are among most dynamic loci in our genome. Like most of the microsatellites, these are considered to be neutral markers, but there are examples that they play essential roles. A few lie in the coding regions, encoding repetitive, and highly variable proteins.

### Satellite

They are also called macrosatellite. They are large tandem arrays spanning hundreds of kilobases to megabases, composed of repeat units of wide range of sizes that can display a higher-order structure. Alpha satellite or alphoid DNA is a good example. It is 170 bp in length. Their detailed structure is difficult to study due to their size and repetitive nature.

### Telomere-Repeat Arrays

Telomeres are the structure present at the end of chromosomes having tandem arrays of hexanucleotide repeat TTAGGG, typically 10–15 kb in length. One end of this array is contiguous with subtelomeric DNA, while other is the true end of the chromosome.

### Chromosomal Rearrangements

Chromosomal rearrangement involves deletions, duplications, inversion and translocations which are caused by either breakage of DNA double helices at two different points, followed by the rejoining of the broken ends or through crossing over between repetitive DNA sequences to produce a new chromosomal arrangement of genes. Chromosomal rearrangement may lead to disruption of genes and implicated in many human

disorders particularly cancer like chronic myelogenous leukemia where balanced translocation results in fusion of the breakpoint cluster region (BCR) with the c-abl (ABL1) proto-oncogene tyrosine kinase leading to the formation of BCR-ABL fusion transcript which constitutively activates tyrosine kinase that can transform cells and inhibit apoptosis (Ren 2005). Chromosomal rearrangement is also a common mode of speciation mainly through post-mating reproductive isolation, e.g., inversion resulted in species diversity between two closely related drosophila species, *Drosophila pseudoobscura* and *Drosophila persimilis*. Gene duplication (16A) also causes bar eye phenotype in drosophila.

### Techniques for Detecting Genomic Variations

Genotyping provides a measurement of the genetic variation between members of a species. Genomic variations are often found to be the etiology of many human diseases and are of particular interest in pharmacogenomics. The increase in interest in GV has been reflected by the rapid development of a diverse range of SNP genotyping methods (summarized in Fig. 1).

### Genetic Variation,

**Fig. 1** List of techniques used for detecting genetic variations

#### Hybridization based methods

- Dynamic allele specific hybridisation
- Molecular beacons

#### Enzyme based methods

- Restriction fragment length polymorphism
- PCR based methods
- Flap endonuclease
- Primer extension

#### Methods based on physical properties of DNA

- Single strand conformation polymorphism
- Temperature gradient gel electrophoresis
- Denaturing high performance liquid chromatography

#### High throughput techniques

- Sanger sequencing
- Next generation sequencing

## Applications of Genomic Variations

### Screening for Genetic Diseases

GV can cause many diseases in humans. These diseases are usually rare but fatal, and an example is cystic fibrosis, caused by mutations in the *CFTR* gene. Many common diseases such as heart disease and cancer are genetically complex, with alleles from several genes contributing to the disease. Linkage and association studies are used to conduct genetic tests for screening of diseases which involves profiling of disease causing variants (Taylor et al. 2001).

### Pharmacogenomics

GV in patients make them respond differently to a medication. In the future, the most appropriate drug for an individual could be determined in advance of treatment by analyzing a patient's SNP profile and such kinds of treatment which are specific for an individual are called "personalized medicines."

### Biological Markers

Often GV tend to be relatively stable genetically; they serve as excellent biological markers. Constructing a chromosome map that shows the positions of known genes with genetic markers allows researchers to study and pinpoint disease traits.

### Forensic Technologies

Genetic profiling of biological material has become one of the most powerful tools for solving parental disputes and in criminal investigations. Traditional methods in DNA "fingerprinting" is now replaced by polymerase chain reaction (PCR)-based technology which detects very short polymorphic stretches of DNA.

## Conclusion

Subtle differences in DNA are the ultimate cause of genetic variation. They may include single-nucleotide polymorphisms, variable numbers of tandem repeats, and large-scale copy number variants. Both inherited and *denovo* variations could

be either advantageous or deleterious for an organism. Beneficial variations are selectively favorable and allow an organism to adapt in changing environmental conditions and hence drive evolution. Studies of these variations are directly relevant in understanding many features of human populations. The structure of populations in terms of inbreeding and reproductive isolation, the relationship of different populations to each other, and the geographical and historical origins of populations – all these aspects are illuminated by studies of genetic variation. Now with the advancement of next-generation sequencing technologies, vast amount of data is available which is being utilized for screening of genetic diseases and for designing personalized medicines. Despite of numerous technical advances, many variations still may exist in the genome which needs to be discovered to fully understand the distribution, pattern, prevalence, and evolution.

## Genome

A genome is an organism's complete hereditary information. It is present in nucleus and also in mitochondrial DNA and present in RNA in some viruses. Human genome contains 23 pairs of chromosomes (22 autosomes and a pair of sex chromosome). Males contain both X and Y sex chromosome and females have XX sex chromosome in their genome. Coding genes and noncoding regions are identified within the genome. In 1944, DNA was shown to be the hereditary material, and in 1953, the concept of double helix was acknowledged. Genetic makeup of an organism lies in DNA sequences which differs in every individual at least at some places.

### Some Facts Regarding Human Genome

- Diploid, 23 chromosome pairs, shows biallelic expression
- $3 \times 10^9$  bases  $\approx$  30,000 genes
- Coding genes represent  $\approx$  1.5–2% of genome sequence
- Repetitive DNA  $\approx$  50%
- 8% present in large recent duplications

## Genomics

Molecular characterization including structure, function, and interaction of whole genome is termed as genomics. Contrast to genetics, where few genes are studied, genomics includes the study of several genes or entire genome of an organism. It needs complex and sophisticated methods to study the genome.

Genomes in Medical Research

By comparing genomes of pathogenic and non-pathogenic strains of a particular microorganism, it's possible to find out the determinants of virulence. Similarly we can compare the genome of virulent strains and the host in order to design drugs targeting the protein products of pathogen-specific genes that have little or no side effect on the host. In addition to this, genome sequencing has an impact on day-to-day practice of medicine and agriculture as to gather information regarding organisms that colonize, feed, and infect homo sapiens.

History of Human Genome Project (HGP): A Book of Life

The gaining of vast knowledge in genomics is attributed to human genome project (HGP). It was a global collaborative effort to clone, sequence, and map the whole human genome. With the establishment of genetic engineering techniques came the HGP, launched in 1990. It was a 13-year project launched by the US Department of Energy (DOE) and National Institutes of Health (NIH) in coordination with international partners to sequence the entire three billion bases in human genome. DOE participated in this project to study the effects of radiation (due to usage of atomic bombs during World War II) on health, more precisely at DNA level. Eighteen countries participated, and the overall budget of three billion dollars was allocated for this coordinated project. DNA of five subjects from different ethnical background were selected for sequencing. Human genome has approximately  $3 \times 10^9$ bp, so enormous amount of data expected to be generated necessitated the use of rapidly processing and DNA sequencing machines and high speed computational devices for data storage, retrieval, and analysis in mapping human genome. It was associated with additional sequencing projects of microbes, plants, mouse, fugu fish, etc. It has to assemble 12,000 bases every minute. Achieving goals of HGP would have been impossible without technological

advancement and collaborative efforts. The entire data is available in public databases in World Wide Web for free access. By 2000, Craig Venter (from Celera Genomics) and Francis Collins (from National Human Genome Research Institute, NHGRI) jointly announced the draft completion of human genome sequencing. In February 2001, the HGP consortium published the first draft of human genome sequence in the journals *Nature* and *Science* (International Human Genome Sequencing Consortium 2001; Venter et al. 2001). Craig Venter was the first named person to get his own genome sequenced. The whole sequence was deposited in GenBank, a public database of DNA sequence operated by National Institutes of Health (NIH) for free access.

Data of few Organisms Studied in Human Genome Project

| Organisms                                  | Genome size<br>Million base pairs (Mb) | Estimated number of genes |
|--------------------------------------------|----------------------------------------|---------------------------|
| <i>Escherichia coli</i>                    | 4.6                                    | 4,300                     |
| <i>Drosophila melanogaster</i> (fruit fly) | 165                                    | 13,300                    |
| <i>Mus musculus</i> (mouse)                | 3,000                                  | 30,000                    |
| <i>Homo sapiens</i> (human)                | 3,200                                  | 25,000–30,000             |

Genome sequences of >5,000 biological entities, ranging from viruses and bacteria to plants and animals, have been reported. By 2011, >180 eukaryotic, prokaryotic, and archaeal genomes had been sequenced, e.g., genomes of chicken, cat, dog, elephant, rat, rabbit, orangutan, etc.

Bioinformatics in HGP

The challenge posed by multifactorial diseases demands a quantum increase in depth of our knowledge of living organisms and we must be able to trace factors both external and internal that compromise health by analyzing genetic,

environmental, and dietary factors across entire community. So, scientists have turned to sophisticated computational tools to collect and analyze biologic information on mass scale (owing to massive size of human genome,  $3 \times 10^9$  nucleotide base pairs) through a process called bioinformatics. This includes all aspects of gathering, storing, handling, analyzing, interpreting, and spreading vast amounts of biological information in databases. The information involves gene sequences, biological activity/function, pharmacological activity, biological structure, molecular structure, protein-protein interactions, and gene expression. It provides rich information from basic metabolism to evolution to aging.

### Goals of Human Genome Project

- Identify all the app. 20,000–25,000 genes in human DNA (15,000 full-length human genes identified).
- Mapping and sequencing the genomes of model organisms like mouse, drosophila (fruit fly), the first plant *Arabidopsis thaliana* (thale cress), chimpanzee, *Caenorhabditis elegans* (roundworm), pathogens, domestic animals, etc.
- Determine the sequences of the three billion chemical bp that make up human DNA (99% human DNA sequence finished to 99.99% accuracy).
- Store this information in databases.
- Improve tools for data analysis.
- Research training.
- Transfer related technologies to other sectors, such as industries.
- Address the ethical, legal, and social issues (ELSI) that may arise from the project. With new tools in genomics, ELSI also arises, so as to use this knowledge in an appropriate and beneficial way, questions that arise are:
  - How to interpret this information and use it?
  - Who should have an access to it?
  - If not used properly, how people can be protected from the associated harm? effect on race and ethnicity should also be considered

So, based on these issues, need for certain public policies development also arises including the philosophical and ethical consequences of understanding our own DNA blueprint.

### How They Sequence DNA?

- (A) DNA polymerase binds to a single-stranded DNA template and synthesizes a complementary strand of DNA.
- (B) When DNA polymerase randomly incorporates a fluorescently labeled ddNTP base, synthesis terminates. This step produces a mixture of newly synthesized DNA strands that differ in length by a single nucleotide. Each strand is labeled at the 3' end with a fluorescently labeled ddNTP base.
- (C) The DNA mixture is separated by electrophoresis.
- (D) The electropherogram results show peaks representing the color and signal intensity of each DNA band. From these data, the sequence of the newly synthesized DNA strand is determined.

### Methodologies of Genome Project

- Genetic mapping
- Physical mapping
- cDNA sequencing
- Genomic sequencing

Major approaches utilized in HGP for sequencing and annotating DNA were:

1. Expressed sequence tags (EST) identify all the genes that are expressed as RNA. This is a blind approach of simply sequencing the whole set of genome that contained all coding and noncoding sequences and later on assigning different regions in sequence with a particular function, i.e., called sequence annotation.
2. Single nucleotide polymorphisms (SNPs)/snips. Scientists have identified around 3 million snips out of 15 million.

3. Clone by clone method: Creating a crude physical map of the whole genome by restriction mapping before sequencing. The approach involved breaking the genome into overlapping fragments and inserting them into BACs and transfecting into *E. coli*. After collecting clones using DNA recombinant technology, a genomic library is developed and physical maps were prepared after organizing these clones into overlapping groups.
4. Craig Venter, one of the leaders of the project, suggested a new method called shotgun sequencing (Venter et al. 1998) for long DNA strands as Frederick Sanger sequencing (DNA sequencing, i.e., a process of reading nucleotide sequences using dideoxy Sanger's method or chain termination method) used earlier can only be used for short DNA strands up to 100–1,000 bps. Shotgun sequencing is analogous to rapidly expanding, quasi-random firing pattern of shotgun. Two main methods are there for this fragmentation and sequencing process, using random fragments. Here, DNA is broken randomly into numerous small segments which are sequenced using chain termination method to obtain reads. Multiple overlapping reads for target DNA are then obtained which are further analyzed through various computer programs and then assembled into continuous sequence.
5. Other essential tools include features from genome map.

The whole genome was read at four- to fivefold coverage to avoid gaps and mistakes in sequence.

## Applications of HGP

1. Chromosomal mapping.
2. Linkage analysis.
3. To study the migration of different population groups.
4. Microsatellites (e.g., variable number of tandem repeats (VNTR)) study is useful for fingerprinting in forensic medicine.

5. HapMap project (International HapMap 3 Consortium & Frazer 2007) to study the SNP (more than 20 million SNP found in human genome) patterns in relation to disease pathogenesis
6. Polymorphism (SNP, copy number variants (CNV), insertions/deletions, inversions) to study risk assessment like early predisposition of disease.
7. Genome-wide association studies (GWAS) to detect common gene variants
8. Cancer genome project – DNA markers help in forming a panel/genetic profile for specific cancers.
9. Genetic counselling – To reduce the likelihood of genetic disease transmission.
10. Personalized medicine.
11. Pharmacogenomics to rationalize drug design.
12. Laboratory diagnostics.
13. Most of the model organisms (*C. elegans*, *Drosophila*) for medical research have conserved regions of genome similar to human genome in evolution (easy to maintain and quick to breed in research laboratories).
14. To identify endangered and protected species – Serves as an aid to wildlife researchers.
15. Agricultural research – To develop disease- and drought-resistant, highly productive breed of plants and seeds.

## Achievements Following the HGP Completion

ENCODE (Encyclopedia of DNA Elements) project was initiated to explore the noncoding sequence (approximately 98% of the genome). It identified many functional elements present throughout the noncoding regions of genome.

Considering the high cost spent for sequencing in HGP, few companies developed the sequencing machines with high throughput, speed, and accuracy at an affordable cost. With the advent of next-generation sequencing (NGS), the whole genome can be sequenced now within a day with much lower cost. Several genome projects like “1000 genome project”

which studied the genetic variation among genome of large number of people, “Genome 10k project” which aims at assembling genome of 10,000 vertebrate species of specific genus, and “i5k project” through which genomes of 5,000 insects and arthropods are to be sequenced in a period of 5 years were launched. Through GeneSweep, the information regarding sequence of human genome increased. So many species genome sequencings are still ongoing.

### What We Learnt Out of HGP?

Through this blueprint, it was found that only less than 2% of the genome codes for proteins. Remaining regions may contain regulatory and repetitive or junk sequences. Almost 99.9% of genome is the same in all people. Size of the genome does not correspond to the number of genes. Most of the translated regions for proteins are conserved in evolution among various organisms. Human genes are just twice in number compared to a fruit fly. ChIP-seq, DNase I hypersensitivity, RNA-seq, and DNA methylation assays were used in ENCODE project (ENCODE Project Consortium 2011).

### Limitations

Obtaining the blueprint alone may not explain the effect of other factors like environment and the role of epigenetics in multifactorial disease, where the genome sequence remains unchanged.

### Conclusion

HGP cannot be concluded, as it is constantly expanding and will be continuing further to fill the gaps and errors. It revealed the extraordinary valuable information about the role of an organism’s genome in evolution, in physiology, and in disease. The HGP was possible with the advent of newer computational and molecular technologies. The cost and time for genome sequencing are

becoming much lesser. A simple blood test to obtain the data of genome sequence will provide a complete genetic profile that predicts the individual’s susceptibility to a disease, responsiveness to a drug, etc. This elaborate database can be effectively applied in emerging field of personalized medicine, after considering the pros and cons.

### Synonyms

DNA methylation; Epigenetics; Gene imprint;  
Non-Mendelian inheritance

### Definition

Genomic imprinting is an epigenetic phenomenon which results in the monoallelic expression of a gene depending on the parental origin. Genomic imprints may be covalent (DNA methylation) or noncovalent (DNA-protein and DNA-RNA interactions, genomic localization in nuclear space) and the process of imprinting encompasses the specialized nuclear enzymatic machinery which maintains parental epigenetic marks throughout the life.

### How Imprinting Works?

All of us inherit two copies of a gene—one copy from mother and another one from father. Normally, both copies are active, whereas in some situations only one of them is turned on. Of these, some genes are active only when they are inherited from father, while others will be activated when inherited from mother. So which copy will remain active depends on their parental origin. These genes are called “imprinted genes.” Genomic imprinting is reversible: a man may inherit a particular allele with a maternal imprint from his mother, but when he passes it on to his child, it will then carry a paternal imprint (Fig. 1).

In imprinted genes, the parent of origin is often marked, or “stamped,” on the gene during the formation of egg and sperm. This stamping

process mostly involves methylation, which turns the gene off, and demethylation which makes the gene active. Most imprinted genes are developmental genes which affect fetal growth, nutrient transfer through placenta, cell proliferation, and brain development. Usually growth-related genes are maternally imprinted.

### Evolution of Genomic Imprinting

Genomic imprinting was first recognized in mammals in 1984 when pronuclear transplantation experiments showed that both maternal and paternal genomes are needed for the normal development of mouse embryos to term (McGrath and Solter 1984). In parallel, mouse genetic experiments provided strong evidence that in some regions of the genome, genes function differently when inherited maternally than when inherited paternally. This provided an explanation for earlier genetic findings (Cattanach and Kirk 1985).

This phenomenon evolved in mammals over 125 million years ago (Killian et al. 2000). The most prominent evolutionary explanation for the origin of genomic imprinting is the “Kinship Theory of Imprinting”. According to this theory, imprinted gene expression is the result of an evolutionary conflict between the maternally and paternally derived alleles within an organism to control the maternal expenditure of resources to the offspring. This battle for resources continues even after birth (Haig 1996). Paternally expressed imprinted genes are meant to promote growth while it is suppressed by maternal genes. By contrast, “Coadaptation Theory” proposes that imprinted genes act co-adaptively to optimize fetal development as well as maternal health and nutrition (Wolf and Hager 2009).

### Mechanism of Genomic Imprinting

Parental imprints are established during gametogenesis when parental imprints are erased and reset. The differential imprinting in gametes correlates with differences in the epigenetic state of the two alleles which is established by DNA

**Genomic Imprinting, Fig. 1** Inheritance of imprinted genes across generations

methylation at CpG dinucleotides, as well as histone modifications. The differential allele expression may occur in all somatic cells, or in specific tissues and stages of development. DNA

methylation is an epigenetic mechanism that occurs by the addition of a methyl ( $-\text{CH}_3$ ) group to DNA, thereby often modifying the function of the genes and affecting gene expression.

**Genomic Imprinting,**  
**Fig. 2** Mechanism of DNA  
 methylation

The covalent addition of methyl group at the 5'-carbon of the cytosine ring is the most common method of DNA methylation. As a result of this covalent addition, 5-methylcytosine (5-mC) is formed (Fig. 2). These methyl groups inhibit transcription by interfering with the major groove of DNA. Different members of the DNMT family of enzymes act either as *de novo* DNMTs (DNMT3a and DNMT3b), putting the initial pattern of methyl groups in place on a DNA sequence, or as maintenance DNMTs (DNMT1), copying the methylation from an existing DNA strand to its new partner after replication. Methylation results in suppression of gene expression, whereas unmethylated genes remain active. The promoter region of the imprinted gene is differentially methylated during gametogenesis in most of the cases.

### Imprinted Gene Organization and Regulation

Imprinted genes are usually organized in clusters containing 2–15 genes and vary in size from <100 kb to several megabases. All clusters contain both maternally and paternally expressed genes, as well as genes that encode proteins and those that encode long noncoding RNAs. Molecular organization of two important imprinted gene clusters in human is shown in Fig. 3. Imprinted genes show exclusive or predominant expression from either the maternal or the paternal allele with an exception of growth factor receptor-bound protein 10 (*Grb10*) gene. Latter encodes an adaptor protein which is predominantly maternally expressed and acts as a growth inhibitor during

embryogenesis, but is paternally expressed in the brain and regulates adult social behavior. Imprinting is under the overall control of a *cis*-acting imprinting control region (ICR). This region shows parent-specific silencing and activation of genes. The germline methylation is robust and resistant to the extensive reprogramming of the genome that occurs in the embryo after fertilization, but is erased and reset during germ-cell development in adults. Most ICRs acquire methylation in the female germ line during oogenesis, and these ICRs typically contain the promoters of long noncoding RNA (lncRNA) genes that run antisense to at least one of the protein-coding genes within the cluster (Fig. 3). ICRs that acquire methylation in the male germ line seem to be located in intergenic regions. An ICR is active when un-methylated and inactive when methylated. The mechanisms by which un-methylated ICRs control imprinted gene expression are only partially understood and two different models, i.e., the lncRNA model and the insulator model, have been described. Only a small percentage of all human genes undergo genomic imprinting. It is still a question that why some genes are imprinted and others are not. Around 150 genes are known to be imprinted in mouse (Mouse book imprinting catalogue), and nearly 70 imprinted genes have been verified in humans (Catalogue of parent of origin effect in human).

### Genetic Mapping of Imprinted Genes

Mouse genetics experiments have shown that mouse embryos have been generated which

**Genomic Imprinting, Fig. 3** Schematic representation of molecular organization of major gene clusters in humans (a) 4 Mb region of chromosome 15 (15q11-13) with at least 10 genes of which 9 are paternally expressed and 1 maternally expressed. There are two components of ICR; one specific to Angelman Syndrome (AS-ICR) and another for Prader-Willi syndrome (PW-ICR). They are differentially methylated and govern which genes are to be paternally or maternally imprinted. The paternal allele encodes a huge transcript (up to 460 Kb and 148 exons) with multiple splice forms under PW-ICR. The first 10 exons encode two proteins, *SNURF* (*SNRPN* Upstream Regulating Frame) and *SNRPN* (Small Nuclear Ribonucleo Protein), while downstream exons lack ORF and some of the introns encode sno RNA (small nucleolar RNA). The downstream part of transcript overlaps the *UBE3A* gene (Ubiquitin ligase) on the opposite strand and possibly acts as an antisense RNA, preventing transcription of *UBE3A* from paternal allele. **Lack of paternal copies of *SNURF* and *SNRPN* is the cause of Prader-Willi syndrome, whereas lack of a maternal copy of *UBE3A* causes Angelman**

**syndrome (b)** 1 Mb region of chromosome 11p15.5 imprinted regions. It contains two differentially methylated regions (DMR1 and DMR2). CTCF (CCCTC-binding factor) binds to unmethylated alleles of both DMRs. In DMR1, there are two imprinted genes: *H19* and insulin-like growth factor 2 (*IGF2*). *IGF2* is a paternally expressed fetal growth factor and *H19* is a noncoding RNA. The *H19*-associated imprinting center (IC1) is usually methylated on the paternal chromosome and unmethylated on the maternal chromosome. Normally, the *H19* gene is expressed from the maternal allele and *IGF2* from the paternal allele. DMR2 contains several imprinted genes, including *KCNQ1*, *KCNQ1OT1*, and *CDKN1C*. DMR2 contains the promoter for *KCNQ1OT1*, a paternally expressed noncoding transcript that regulates in cis the expression of the maternally expressed imprinted genes in this region. **Disturbance of genomic imprinting due to loss or gain/loss of methylation on maternal/paternal allele is responsible for Beckwith-Wiedemann syndrome and Russell-Silver Syndrome**

contained a small proportion that were derived either from paternal or maternal source. The generation of a series of such uniparental

disomies, which simultaneously span the entire genome allowed the generation of an imprinting map. More than 50% (approximately 80%)

**Genomic Imprinting, Table 1** List of diseases associated with imprinted genes in humans

| SN | Syndrome                                    | Chromosome location              | Major features                                                                                                                                                                                                                                              | Cause                                                                                                                                                                                                                            |
|----|---------------------------------------------|----------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 1. | Prader-Willi syndrome                       | 15q11-13                         | Short stature, obesity, hypogonadism and learning difficulties                                                                                                                                                                                              | Interstitial deletion of ~2Mb proximal region of long arm of paternal chr 15 or maternal UPD of chr 15                                                                                                                           |
| 2. | Angelman syndrome                           | 15q11-13                         | Epilepsy, severe learning difficulties, unsteady or ataxic gait and happy affect                                                                                                                                                                            | Interstitial deletion of ~2Mb proximal region of long arm of maternal chr 15 or paternal UPD of chr 15                                                                                                                           |
| 3. | Beckwith-Wiedemann syndrome                 | 11p15.5                          | Macrosomia (prenatal and postnatal overgrowth, macroglossia (large tongue) omphalocele, umbilical hernia diastasis recti, neonatal hypoglycemia, renal and ear abnormalities, cleft palate and predisposition to embryonal tumors particularly Wilms' tumor | Complex epigenetic error leads to loss of maternal <i>H19</i> expression and paternal biallelic <i>IGF2</i> expression along with reduction in <i>CDKN1C</i> expression or paternal UPD11                                        |
| 4. | Russell-Silver syndrome                     | 11p15.5(65% cases) MatUPD7 (10%) | Prenatal and postnatal growth retardation, triangular face with pseudohypocephalic appearance                                                                                                                                                               | Hypomethylation of <i>H19</i> DMR results in <i>IGF2</i> silencing and biallelic expression of <i>H19</i> or Maternal UPD7; <i>MEST</i> and <i>GRB10</i> are candidate genes for MatUPD7                                         |
| 5. | Pseudo-hypothyroidism type 1a               | 20q13.3                          | Dysmorphism, obesity, cognitive impairment, end-organ resistance to PTH (which results in hypocalcemia and hyperphosphatemia)                                                                                                                               | Maternal inactivating mutations of <i>GNAS</i> result in 50% expression of non-imprinted <i>GNAS</i> , which causes the dysmorphic phenotype AHO; loss of imprinted <i>GNAS</i> expression causes obesity and hormone resistance |
| 6. | Pseudo-hypothyroidism type 1b               | 20q13.3                          | End-organ resistance to PTH (which results in hypocalcemia and hyperphosphatemia) and occasional resistance to TSH                                                                                                                                          | Lack of maternal <i>GNAS</i> methylation imprinting results in loss of expression of imprinted <i>GNAS</i>                                                                                                                       |

imprinted genes are found in clusters, indicating a coordinated control (Reik and Walter 2001). These clusters are known as imprinting domains. Currently, genome-wide screenings identify imprinted genes by using following methodologies:

1. Differential expression of mRNAs from control fetuses and parthenogenetic or androgenetic fetuses hybridized to expression arrays (Kobayashi et al. 2009).
2. Allele specific gene expression using SNP genotyping arrays (Bjornsson et al. 2008).

3. Transcriptome sequencing (Babak et al. 2008).
4. *In silico* prediction pipeline (Luedi et al. 2007).

## Genomic Imprinting and Genetic Disorders in Humans

The growth of embryos in human is regulated by many imprinted genes which also regulate the development. Deviation from monoallelic expression of imprinted genes leads to severe developmental defects in humans (listed in Table 1). Many disorders also occur due to a unique phenomenon known as uniparental disomy (UPD) of the chromosomes having imprinted genes. If an individual inherit both homologs of a chromosome pair from one of their parent then it is called uniparental disomy. UPD leads to either loss of expression of a gene or bi-allelic expression of the gene, hence loss of genomic imprinting.

## Genomic Imprinting in Other Species

Genomic imprinting is unique to therian mammals (placental mammals and marsupials) and flowering plants. Imprinting of whole chromosomes has been reported in mealybugs (Genus: *Pseudococcus*) and a fungus gnat (*Sciara*). It has also been established that X-chromosome inactivation occurs in an imprinted manner in the extra-embryonic tissues of mice and all tissues in marsupials, where it is always the paternal X-chromosome which is silenced.

## Conclusion

Genomic imprinting is the mechanism through which a gene or a genomic domain is stamped biochemically with information about its inheritance. There is biased allelic expression due to imprinting that favors expression from one parental locus over other. Though majority of the imprinted genes code for protein, there are some which code for untranslated RNA transcripts. Genomic imprints violate Mendel's laws of inheritance, one of which stipulates that the

dominance of one genetic allele over another is an inherent function of the alleles themselves and does not depend upon the parent of origin. Loss of imprinting lies at the root of many human disorders. They may also be involved in the development of common diseases such as obesity, diabetes mellitus, and cancer. To fully comprehend the role of imprinted genes in biology and disease, a complete list of imprinted genes is needed.

## Definition

The set of genes in our DNA which is responsible for a particular trait is referred to as genotype. Hence, it is the information stored within a gene.

## Introduction

The word genotype can be used to refer a particular gene or set of genes which are carried by an individual. Genotype of an individual is its complete heritable genetic identity, which is unique to an organism or individual. It also refers to the alleles or variants of a gene, which are carried by an organism. Humans are diploid organism, which means they have two alleles at a given locus, wherein one comes from father and the other one from mother. These alleles represent the genotype of a specific gene. Genotype, along with epigenetic factors, determines the phenotype.

Genotype is internally coded inheritable information which is carried by all organisms. This coded information is used as a blueprint for building and maintaining a living creature. This information is present in all cells and is passed on to

next generation at the time of cell division. These coded instructions control everything such as formation of protein, regulation of metabolism. In contrast to genotype, phenotype is the outward physical manifestation. It may include physical parts, energy utilization, tissues, organs, reflexes and behavior, therefore anything which is part of the observable structure, function, or behavior of living organism can be a part of phenotype.

The examples of genotype include genes responsible for the stripes on cat, size of a bird's beak, height, hair color, eye color, etc. Let us assume the eye color of human being; we have different colors like blue, brown, green, black, etc. Why we all have a different eye color? This is because of the difference in the amount of eye pigment, **melanin** which is present in iris. Eye color is an inherited trait and there have been evidences that up to 16 genes can influence the color of eye (Sturm and Larsson 2009). There are three known alleles that control the shade of eye color. These alleles assort independently during gamete formation. Every individual has four alleles for controlling their eye color; B allele (brown) is always dominant over G allele (green). The blue trait is always recessive (Table 1).

From the above Table, we can see that two or more than two different genotypes can give the same phenotype, so two different individuals having brown eyes may have different genotype. The inheritance pattern in albinism and hemophilia can also be taken into account for correlating genotype and Mendelian inheritance.

**Genotype, Table 1** Genotype and phenotype of eye color

| Genotype | Phenotype |
|----------|-----------|
| BGG      | Brown     |
| BbGG     | Brown     |
| BBGg     | Brown     |
| BbGg     | Brown     |
| BBgg     | Brown     |
| Bbgg     | Brown     |
| bbGg     | Green     |
| bbGG     | Green     |
| Bbgg     | Blue      |

## Genotypic Ratio

The number of times a genotype would appear in the offsprings after a cross between both parents will be the genotypic ratio. The value depends upon the genotype of parents. It can be calculated by Punnett square. Let us assume that two organisms with same genotype (Aa, A is dominant and a is recessive) are allowed to mate, the offsprings will have the genotype: AA, Aa, and aa and the resulting genotypic ratio will be 1:2:1, whereas the resulting phenotypic ratio will be 3:1 (Fig. 1).

## Genotyping

The process of determining differences in the genetic make-up of an individual by examining an individual's DNA sequence and comparing it to another individual's sequence or a reference sequence is known as genotyping. The most widely used methods for genotyping include polymerase chain reaction (PCR), DNA sequencing, random amplified polymorphic detection (RAPD), amplified fragment length polymorphism, allele-specific polymerase chain reaction, and hybridization to DNA microarrays. Genotyping finds its application in prenatal disease diagnosis, for which two widely used techniques are "amniocentesis" (Hessner et al. 1998) and "chorionic villi sampling." Apart from prenatal disease diagnosis, genotyping is routinely used for determining blood group, genetic counseling, and personalized medicine. Genotyping can be done right from humans to microorganisms. For

microorganisms, genotyping can be used for controlling the spreading of pathogens. Similarly transgenic organisms can also be genotyped. A transgenic mouse can be genotyped by a simple polymerase chain reaction (PCR) technique.

## Effect of Environment on Genotype

Genotype of an organism is its inherited map which is carried within its genetic code. All organisms that have the same genotype do not look or behave the same way as phenotype and behavior are modified by environmental factors. When two different genotypes respond to environmental factors in a different way, it is referred to as gene environment interaction. Such interactions can provide a better insight for the genetic epidemiology of certain diseases. We all know that every individual may have different response to a particular drug due to gene environment interactions. Here, now the term pharmacogenetics (Klotz 2007) comes into picture, which is the study of inherited genetic differences in drug metabolic pathways which generally affects the individual responses to drugs. Hence, it will allow clinicians to select the drug and its dosage more precisely.

## Conclusion

Genotype is the entire set of genes in a cell, an organism, or an individual. It depends on the genetic information which was given to an individual by their parents. An individual's genotype is indicative of their full genetic information which is determined by the genes passed on by the parents. Children born to a parent will have different genotype, the exception to this are twins or multiple births that are fertilized from same egg. Genotype determines the type of trait that a phenotype can have and it is the major influencing factor in development of phenotype. The concept of phenotypic plasticity can explain the degree to which an organism's phenotype is determined by its genotype. Phenotypic plasticity is the changes in an organism's behavior, physiology,

**Genotype, Fig. 1** Punnett square showing the genotypes of offsprings when parents have the same genotype

and morphology due to its adaptation to a unique environment. There is another contrasting term as compared to phenotypic plasticity, known as genetic canalization which explains about the extent to which an organism's phenotype allows conclusions about its genotype.

## Definition

**Genus** is a Latin word, which was popularized by Swedish scientist *Linnaeus* in his 1753 *Species Plantarum*. But “the founder of the modern concept of genera” is a French botanist *Joseph Pitton*

*de Tournefort* (1656–1708). “Genus” (plural “genera”) is a principle taxonomic classification, which lies in between the family above and the species below and comprising of species that are structurally or phylogenetically related to each other or an isolated species.

## Introduction

### Taxonomy/Taxonomic Hierarchy

*Carolus Linnaeus* (1707–1778), a Swedish botanist, first used the term Systematics, which is defined as the study of various organisms' identification and relationships. Later during the eighteenth century, “Taxonomic Hierarchy” was introduced by *Linnaeus*, a unique classification system of all living organisms. The classification given by him is being pursued all around the world now. Linnaeus is considered the father of modern taxonomy and classification. AP De Candolle gave the term “Taxonomy” **in the year 1813**, which is derived from an ancient Greek word “taxis” meaning arrangement and “nomos” meaning law or method (Kotpal 2013). Taxonomy is a scientific method of naming, describing, and classifying all living organisms (plants, animals, and microorganisms) in an ordered system that indicates natural relationships. In simple words, “Taxonomic hierarchy is defined as the process in which various organisms are arranged into successive levels of the biological classification either in a decreasing or an increasing order from kingdom to species and vice versa” [Fig. 1] (The Editors of Encyclopedia Britannica 2017). Taxonomy is one of the oldest most fundamental branches of biology. New species of animals and plants are being identified every day, and their classification and characters are studied with the help of taxonomy.

### Taxonomic Rank/ Category

Carl Linnaeus also developed a binomial nomenclature system of animals and plants in his first remarkable publication, “*Systema Naturae*” **in 1735** (Kapoor, 1998). This book is known as the “dictionary of classification.” Linnaeus used some taxonomic ranking or levels under this

**Genus, Fig. 1** Showing taxonomic hierarchy categories

classification, which included *kingdom*, *phylum*, *class*, *order*, *family*, *genus*, and *species* (Fig. 1). Also, Carl Woese proposed another level named the *domain*, a crucial rank now being used widely. Each level of the hierarchy is called the taxonomic category or rank, where the highest rank is given to the kingdom and the lowest rank given to the species. Before Linnaeus, the classification of organisms was somewhat arbitrary, and organisms were often given long names that could be easily altered, making it more difficult for different biologists to understand what species they were referring to. Linnaeus was the first to formulate the classification based on the organism's similarities and designate the binomial system (*genus* + *species*) to classify organisms (Kaburu 2017).

## Binomial Nomenclature

The writing system of all the organisms on earth, living or extinct, introduced by *Linnaeus* is known as "Binomial Nomenclature" or a two-term name. This nomenclature is a unique method of naming organisms and includes two Latin words. The first word of the name belongs to the genus; another word belongs to that specific animal or plant and is called species. Thus the second word is used to

**Genus, Table 1** Showing an example of taxonomic hierarchy

| Taxonomic hierarchy | Example (Human being- <i>Homo sapiens</i> ) | Example (Tiger- <i>Panthera tigris</i> ) |
|---------------------|---------------------------------------------|------------------------------------------|
| Domain              | Eukaryota                                   | Eukaryota                                |
| Kingdom             | Animalia                                    | Animalia                                 |
| Phylum              | Chordata                                    | Chordata                                 |
| Class               | Mammalia                                    | Mammalia                                 |
| Order               | Primates                                    | Carnivora                                |
| Family              | Hominidae                                   | Felidae                                  |
| Genus               | <i>Homo</i>                                 | <i>Panthera</i>                          |
| Species             | <i>Sapiens</i>                              | <i>Tigris</i>                            |

separate each of the species within the same genus. We can use some examples to understand the binomial nomenclature: a very popular bird in India called Gauraiya is named as *Passer domesticus*, the dog is named as *Canis familiaris*, the housefly is *Musca domestica*, and the scientific name of human beings is *Homo sapiens* – genus name is *Homo* ("human being" in Latin) and the species name *sapiens* ("wise"), and it designates all living humans (and their extinct direct relatives); it comes under family Hominidae (Sigwart et al. 2018) (Table 1).

There is a difference between a binomial name and a common or vernacular name. Vernacular name is not standardized and varies by location, whereas binomial name is standardized and is accepted worldwide for the nomenclature of plants and animals. There are different organizations which deal with the nomenclature of animals like ICZN (International Code of Zoological Nomenclature), and body or organization dealing with the nomenclature of plants, algae, and fungi is ICNafp (International Code of Nomenclature for Algae, Fungi and Plants); earlier it was called ICBN (International Code for Botanical Nomenclature). For prokaryotes nomenclature, it is ICNP (International Code of Nomenclature of Prokaryotes); previously, it was called ICNB, i.e., International Code for Nomenclature of Bacteria. The body for the nomenclature of viruses is ICTV (International Committee on Taxonomy of Viruses) (Narendran 2006).

## Rank: Genus

The words species, genus, and family were first used by **John ray**. In taxonomic classification, “genus” is one of the levels used to classify various organisms, including viruses (ICTV Taxonomy 2018). Genus consists of a group of related species with more characters in common than species of other genera. We can say that genera are aggregates of closely related species (Kotpal 2013). For example, potato and brinjal are two different species, but both belong to the genus *Solanum*. Lion (*Panthera leo*), leopard (*P. pardus*), and tiger (*P. tigris*) with several common features are all species of the genus *Panthera*. Genus *Panthera* belongs to the family *Felidae*. This genus differs from the genus of cats *Felis*. If we consider common characteristics, for example, in genus pine (*Pinus*), all the trees would have hard, woody cones with tough, thick scales and long, narrow needles in bundles.

According to modern biological [taxonomy](#), genus lies between species below and the family above (Fig. 1). In binomial nomenclature, each name has two components – the generic (genus) name and the specific epithet. Hence genus represents the first name in the scientific names used for naming any organism around the world. Sometimes between family and species, other categories also are used, such as subgenus (below genus) and subfamily (above genus). The genus name is always capitalized and italicized. For example, mango’s scientific name is written as *Mangifera indica*, where genus is represented by its first name *Mangifera* and second name *indica* represents species or a specific epithet. However, taxonomists define the genus composition for the scientific name of any organism.

## Genus: Two Types

- **Monotypic:** When a genus consists of only one species, then it is known as a monotypic genus. For example, the sea turtle hawksbill is the only member of the genus *Eretmochelys*.
- **Polytypic:** When a genus consists of more than one species, it is known as a polytypic genus.

For example, the genus *Panthera* includes both lion and tiger.

## Use in Taxonomy

Genus is the first name of any organism according to binominal nomenclature, which helped taxonomists to name and classify various animals and plants including viruses and prokaryotes.

### Type Genus

The type genus is the [genus](#), which determines the name of the family or subfamily in biological classification. It is the largest or best-known or earliest-described criteria, although not necessarily the most representative genus. The type genus is commonly used for zoological nomenclature and not used unofficially for the nomenclature of plants where “type genus” is used as a convenience ([ICZN Code art](#)).

### Type Species

In zoological nomenclature, type species is the name of the species, with which the name of a [genus](#) or subgenus is thought to be associated taxonomically, i.e., the species that contains the biological type specimen (International Code of Zoological Nomenclature 1999). Type species is used to describe a genus, mainly modified and expanded by the features of other included species.

## Synonyms

Global geometry; Local geometry; Spatial reorientation

Successful movement between locations first requires the determination of a direction of travel, and understanding the process of determining a direction is the central focus of orientation research. As shown in the top panel of Fig. 1, the general approach to understanding orientation involves training disoriented participants to respond to a particular location within a rectangular enclosure (left). Importantly, this location is often uniquely specified by a distinctive feature. Interestingly, tests in the absence of the distinctive features reveal that participants not only respond to the originally trained location but also to its 180° rotationally equivalent location (right).

Responses to this 180° rotationally equivalent location are termed a *rotational error* (for a review, see Cheng et al. 2013).

The occurrence of the rotational error is particularly interesting because it suggests that participants learn something about the geometric shape of the enclosure itself during training, and such learning about the geometric shape of the enclosure during training is unneeded because it is neither necessary nor sufficient to determine the correct location (for a review, see Cheng et al. 2013). Specifically, the correct location is uniquely and sufficiently specified by the distinctive feature; yet in its absence, participants respond as if they learned the correct location with respect to the environmental shape, and the rotational error is suggested to occur because, in the absence of the distinctive feature, environmental geometry alone cannot disambiguate the correct from the rotationally equivalent location.

The occurrence of the rotational error has been observed in ants, chicks, pigeons, fish, and primates – including human children and human adults (for a review, see Cheng et al. 2013). In human adults, the rotational error also occurs in a sensory modality other than vision (Sturz et al. 2014). Specifically, blindfolded adults trained to respond to a particular corner of a rectangle designated by a unique texture respond to the trained and rotationally equivalent locations when the unique texture is absent. This occurrence across species and sensory modalities suggests that orientation via geometric cues may be a ubiquitous and fundamental process in the animal kingdom (see Tommasi et al. 2012). As a result, determining the nature of this geometric encoding – environmental points, lines, angles, and overall shape to determine a direction – has received considerable research attention (see Sutton 2009), and manipulations of shape from training to testing have revealed two basic categories of geometric cues used during reorientation: *local geometric cues* and *global geometric cues* (see Bodily et al. 2011; Lubyk et al. 2012; Sturz et al. 2012; for a review, see Sutton 2009). Both types of cues explain the presence of the rotational error but differ with respect to what is encoded about environmental geometry.

**Geometric Encoding, Fig. 1** *Top Panels.*

Illustration of the Training and Testing components of the reorientation paradigm. *Bottom Panels.* Illustration of local and global geometric encoding strategies

As shown in Fig. 1 (bottom left), local geometric cues are independent cues such as wall lengths and corner angles that constitute the environmental shape (see Miller and Shettleworth 2007). Thus, local geometric encoding would involve encoding the correct location during training as a location specified by short wall right, long wall left, and 90° corner angle. Such local geometric encoding during training explains the occurrence of the rotational error during testing because both the correct and rotationally equivalent locations are located at the right side of a short wall, the left side of a long wall, and at a 90° corner angle. In contrast, global geometric cues (often derived from computational geometry) are dependent on the overall shape of the environment because they must be encoded from the overall shape of the environment (see Sturz and Bodily 2012). For

example, the principal axis of space, which runs through the centroid and approximate length of the space is a summary parameter derived from the boundaries (see Sturz et al. 2011). Thus, global geometric coding with respect to the principal axis would involve encoding the correct location during training as the location specified by the left side of the principal axis. Such global geometric encoding during training explains the occurrence of the rotational error during testing because both the correct and rotationally equivalent locations are located at the left side of the principal axis. Similarly, the medial axis of space which is a trunk and branch system that captures overall shape information is also derived from the boundaries (see Kelly et al. 2011). Thus, global geometric encoding with respect to the medial axis of space would involve encoding the correct location

during training as the location specified by the terminal end of the trunk's left branch. Such global geometric encoding during training explains the occurrence of the rotational error during testing because both the correct and rotationally equivalent locations are located at the terminal end of the trunk's left branch.

Despite recent debate about which global geometric cue may be encoded (see Sturz and Bodily 2012), it is clear that both local and global geometric cues are encoded and used for orientation (see Cheng et al. 2013). As importantly, it is also clear that a sense component (i.e., left or right) is part of this encoding process (see Sovrano and Vallortigara 2006). Current research is continuing to manipulate aspects of the environment from training to testing to further illuminate the geometric cues used to reorient with respect to the environment.

## Geometric Module

Anthony McGregor  
Department of Psychology, Durham University,  
Durham, UK

The concept of cognitive modularity is crucial to our understanding of the architecture of the mind. One view is that psychological processes such as learning, perception, memory, and judgment are *domain general* such that they are able to interact

with and influence one another. Others argue, to a lesser or greater degree, that the mind is composed of independent *domain-specific* processing modules. Fodor (1983) argued that some perceptual processes follow this modular architecture but that cognitive processes were largely nonmodular. One characteristic of a module is that the information it processes is *encapsulated*; that is, the module is impenetrable to information stored centrally elsewhere, and the central store of information has limited access to the information processed by the module. Thus in an encapsulated module, processing of information is largely independent of information processed elsewhere. A classic example of this kind of modularity is in visual illusions. A person may know the reasons for the illusion but is unable to prevent themselves from experiencing it.

An apparent example of a cognitive process being under the control of an encapsulated module came with Cheng's (1986) influential study on spatial cognition in rats. Rats were placed into a rectangular box that contained food in one of its corners. After finding and eating some of the food, the animals were removed from the box before being replaced and given the opportunity to eat the remainder. In the original study, the rats were replaced in an identical box that differed in its orientation to the first (e.g., rotated 90° clockwise). In later studies, the animals themselves might be disoriented through slow rotations in the dark to achieve inertial disorientation and replaced in the same box. Despite visual and/or odor cues (termed *featural* or *nongeometric*) that could be used to distinguish the ambiguous corners of the rectangle, the rats appeared to ignore these and use only the geometric properties of the

box to relocate the food. This led to the rats searching in the correct corner and also in the diametrically opposite but geometrically equivalent corner. The result was interpreted in terms of a primacy for the use of geometric information over featural information. Because the rectangle was geometrically ambiguous, with two corners that are identical in terms of the arrangement of long and short walls (e.g., corners A and C in Fig. 1), when the animals reoriented, they chose the two geometrically equivalent corners equally – a quirk of the shape selected. This result was replicated in a wide range of taxa from fish to humans (reviewed in Cheng and Newcombe 2005) which led to the popular view that many animals possess a geometric module that serves to represent the global geometric properties of the environment. Cheng showed that with repeated training, featural cues were able to gain control over behavior, but he claimed that this representation was “pasted on” to the geometric representation such that the representation is retained without being altered by the representation of the features. Such a geometric module makes sense from an evolutionary perspective. The features of an environment (e.g., foliage on trees) are likely to change over time, but its geometric layout will not, so it may be adaptive to extract information about the broad geometric shape of the environment without interference from more transient featural cues.

Cheng's study has gone on to influence theories of how humans and other animals orient themselves and navigate with reference to the geometric properties of their environments. However, examples of the use of featural cues for reorientation or the failure to use geometric cues even when they are good indicators of a location

**Geometric Module,**  
**Fig. 1** The geometric layout of arenas in Pearce et al.'s (2004) transfer experiment

have cast doubt on the original formulation of the geometric module as a mechanism for rapid cognitively economic spatial orientation (reviewed in Cheng 2008). The geometric module hypothesis supposes that geometric cues should have primacy for control over spatial behavior, and that featural cues should be unable to interfere with learning about geometric cues. One way of testing this is to test for effects known as cue competition. In associative learning, cues that signal important events, such as the delivery of food, are said to compete for control over behavior. For example, a rat might be trained in a Pavlovian conditioning task that a light signals that food is about to be presented. When the light is illuminated, the rat begins to poke its nose into the hole where the food drops, in anticipation of the food. If another rat were to be trained similarly, but with both a light and a tone signalling the food, it would be expected to learn something about the significance of the light, and something about the significance of the tone. Crucially, however, what is learned about the light restricts what is learned about the tone, and vice versa, indicating that the cues compete for control over the nose-poking behavior. We can test this by presenting both rats with a light and recording the number of nose pokes. Cue competition is said to have occurred if the rat trained with both the light and the tone nose pokes less than the rat trained with the light only.

Attempts to examine these cue competition effects in geometry learning at first met with null results, in line with the geometric module hypothesis. Animals appeared to have learned about geometry regardless of the presence of nongeometric features. However, demonstrations of two forms of cue competition – overshadowing, as described above, and blocking, in which learning about one cue (e.g., a light) in a prior stage subsequently restricts, or blocks, learning about an additional cue (e.g., a tone) when the light and tone are presented in compound – followed in mountain chickadees (*Poecile gambeli*) and laboratory rats when a colored wall restricted learning based on geometry, compared with animals that were only able to rely on geometry (review in Cheng 2008).

Perhaps surprisingly, it was also found in rats that under some circumstances the non-geometric feature actually facilitated learning about geometry (Pearce et al. 2006). Neither of these results was predicted by the geometric module hypothesis, but the latter was also a surprise in terms of the prediction of cue competition. Subsequent work showed that non-geometric and geometric cues come to be associated with one another during training in a within-compound association. The presentation of one cue evokes a memory of the other, which drives responding. The salience of the nongeometric and geometric cues is key to whether cue competition or cue facilitation will be detected. If cue competition is weak because the nongeometric feature is not very salient, then the opposing action of the within-compound association is more readily detected and geometry learning will appear to be facilitated. If cue competition is strong, then the within-compound association will be unable to counteract its effects. Thus results from cue competition studies appear to support an associative domain-general analysis of geometry learning and not a modular account.

Another aspect of the geometric module hypothesis is its characterization of the representation of geometry. Cheng (1986) described his findings in relation to rats encoding the shape of the environment via a metric frame, which has subsequently been allied to the notion of a cognitive map that takes its inputs from the geometric properties of the environment (Doeller and Burgess 2008). A cognitive map is difficult to define, but it could be said to be an internal representation of the global geometric relations among stimuli in the environment, used for navigation through the environment. In these terms, the geometric module should be responsible for forming a representation of the overall shape of the environment. Pearce et al. (2004) tested this idea by training rats to find a submerged platform in one corner (e.g., corner A in Fig. 1) of a rectangular water maze. The water maze was surrounded by curtains and rotated by either 90, 180, or 270° between trials. The point of release also varied between trials, so rats were required to reorient

using some aspect of the geometry of the arena in order to identify the correct corner. Following this training, the overall shape was altered to that of a kite, which contained one corner with the same arrangement of long and short walls as the correct corner of the rectangle (e.g., corner E in Fig. 1), and one with the mirror opposite arrangement of walls (e.g., corner G).

Rats transferred their behavior across the arenas, searching in the corner that shared the same local geometric properties as those of the correct corner in the rectangle. Pearce et al. (2004) argued that rats had relied on a more local representation of space and claimed that an appeal to a global representation was unnecessary. However, their findings did not necessarily rule out that rats were able to use a global map-like representation because the opportunity to act on such a representation was removed by transforming the overall shape. Recently, results in humans (Buckley et al. 2016) have suggested that a global representation of shape is maintained despite performance in a transformed arena that indicated reliance on a local representation of geometry as found by Pearce et al. (2004). Buckley et al. trained human participants to navigate to a target location within a computer-generated arena in the shape of a rectangle. At the end of training, they were transferred to the outside of the arena and asked to go to the location that was closest to the target when they had been on the inside. If the arena in the test trial was the same overall shape as during training, then participants were able to perform accurately. However, if the overall shape had been transformed to that of a kite participants performed at chance, despite the same local geometric cues being present in both test trials. The results are best explained by reference to a global geometric representation. As yet, such a test has not been conducted in nonhuman animals.

The notion of a geometric module is not entirely refuted by the results described above. Evidence of a geometric module in humans is still widely debated, with some arguing that geometric cognition is one of suite of core knowledge components in human cognition (Spelke and Kinzler 2007). Spelke and her colleagues have

put forward a modified version of the geometric module hypothesis that includes information about distance and direction based on surfaces surrounding the environment, but not angle or length, which instead are processed by a landmark system that is responsible for the representation of smaller objects. Cheng et al. (2013) have challenged these claims based on the plausibility of a geometry system that is so selective in the cues that it processes, and the evolutionary advantage such a system would deliver. They also pointed to a wider range of literature than was considered by Spelke and colleagues, including findings from animals. Others have considered the neural systems that process spatial information and concluded that there is a hippocampus-based system for processing boundaries, and a separate striatal system for landmarks (Doeller and Burgess 2008). In common with the geometric module hypothesis, this account predicts that learning based on the geometry of the arena should be unrestricted by learning based on landmarks, but it differs in that it is concerned less with reorientation and more with the representation of location. Ultimately, these accounts of the role of geometric information in spatial cognition demonstrate the limited scope of the geometric module hypothesis: they either reconceptualize the hypothesis so that they constrain the type of information processed in the module, based on a limited corpus of data, or they expand the role of geometry to support a wider range of behaviors (i.e., in navigation to locations) than originally hypothesized. What becomes clear is that it is necessary to apply the role of geometry in spatial cognition more widely than is envisaged within the original modular hypothesis and to consider whether a modular cognitive architecture is necessary to explain apparent independent cognitive processes.

- cognition in animal species (ranging from unicellular organisms to humans). Romanes was also an innovator in the study of the anatomy and physiology of simple nervous systems in marine invertebrates including jellyfish, starfish, and sea-urchins. He suggested that the origination of new species could arise not only through Darwin's mechanisms of natural selection and sexual selection but by a third mechanism he called "physiological selection."

The first part of this entry is a sketch of Romanes's life and background. His research on the nervous systems of invertebrates and his view on physiological selection are covered in this first part. The second part is an account of his theory of the evolution of intelligence in humans, moving progressively from animal to human cognition (including language). The third part outlines some issues in the secondary literature concerning the scientific reception of his ideas.

## A Sketch of Romanes's Life

Romanes's Scottish lineage is traced back to 1586 and to a region southeast of Edinburgh. But we start in 1834, when his father, George Romanes, emigrated to Canada. Romanes was born on 2 May 1848, at 207 William Street, Kingston, Ontario. His father moved into this house in order to teach at Queen's College (now Queen's University). Prior to the move, his father was an Anglican minister in small Ontario parishes not far from Kingston. In Romanes's time, the house was part of the fledgling University that was founded in 1841, and it was here that Romanes's father was a professor of Classics. Protestant Christianity was a prominent part of Romanes's background; not only was his father Anglican, but his mother, Isabella Gair Smith, was the daughter of a Scottish Presbyterian minister. She maintained her Scottish roots and Romanes was later able to establish a laboratory for his "neuroscientific" research in her family house (called "Geanies") at Dunskaith in Scotland, located just north of Inverness, on the North Sea coast, a rich source of marine life. Romanes had three surviving siblings, namely, an older brother James, an

## Introduction

George John Romanes (1848–1894) was an illustrious member of Darwin's circle and a pioneer in the study of the evolution of behavior and

older sister Georgina, and a younger sister Ethel, who later assisted him in some of his behavioral research.

In 1849, his father received information of an inheritance, the wealth having accrued from a family business dealing in Scottish fabrics and textiles. On the same day, the house on William Street was seriously damaged by fire. The Romanes family moved back to Britain in 1850, where they settled in London.

After Romanes entered Gonville and Caius College, Cambridge, in October 1867, he studied mathematics and religion (he originally intended to become a clergyman). He turned to physiology 3 years later under the tutelage of Michael Foster (1836–1907), famed for his work on embryology and on the history of physiology. The importance of Foster's laboratory for the history of science in general has been outlined by Geison (1978). Geison explained that the founding of new laboratories for physiology, and also for physics, at the University of Cambridge was motivated by the fear that Britain was falling behind Germany in the publication and institutionalization of scientific research.

Romanes's first influential experimental research, carried out in Scotland as well as in Cambridge, was on the primitive nerve-nets of jellyfish. In his research on jellyfish, he suggested that the nerve fibres "cross and re-cross one another without actually coalescing" (Romanes 1896/1898, p. 19), a conjecture later substantiated by his physiologist friend E. A. Schäfer. These investigations were the first to establish that jellyfish had a primitive nervous system; they have also been argued by Lesch (1976, p. 517) and Geison (1978, pp. 244–249) to anticipate the discovery of the synapse in the 1890s.

In other research, Romanes investigated the effects of injuring and stimulating the nerves of starfish. He showed that the nervous system in starfish is much more sophisticated than it is in jellyfish, because injury or stimulation of the jellyfish's nerve-net caused a reaction of the whole organism, whereas injury or stimulation of the starfish's nervous system caused movements that could be restricted to a particular body part such as one of the arms. During the

course of this research, Romanes concluded that the key to an understanding of the evolution of intelligence in the animal kingdom resided in appreciating the increasingly specialized role of individual subsets of nerves. This belief, particularly, pertained to enhanced sensory discrimination and the refined coordination of movements. His various articles on invertebrate neuroscience, dating mainly from 1876 to 1881, were summarized in *Jelly-Fish, Star-Fish, and Sea Urchins* (Romanes 1885).

Romanes was also caught up in the excitement over *The Origin of Species* (Darwin 1859/2004), published when Romanes was 11. He was also inspired by its sequel, *The Descent of Man* (Darwin 1871/1899), published 1 year after Romanes had commenced his physiological investigations at Cambridge. A letter to *Nature* (Romanes 1873), written while he was engaged in marine research at Geanies, concerned the evolution of the variety of shadings found in flatfish such as plaice and sole. This letter attracted the attention of Darwin himself, who arranged for a meeting with Romanes. From then on, the two were close friends and colleagues. They frequently visited each other and, in 1881, when Darwin sensed that his death was not far off, he sent Romanes an article titled "A Study of Instincts" for publication as an Appendix to Romanes's book, *Mental Evolution in Animals* (Romanes 1883). Romanes was the last person Darwin called on in London before being confined, because of his terminal illness, to his house in the Kent countryside (Atkins 1974, p. 93).

Romanes moved to London in 1874, where he continued to study physiology under William Sharpey (1802–1880) and John Burdon-Sanderson (1828–1905) at University College. He remained in London for the next 16 years, becoming a Fellow of the Royal Society in 1879, at the age of 31. In that same year, he married Ethel Duncan (1856–1927) of Liverpool and settled into a house a few doors down from the house his father moved into in 1850; they had six children. While he resided in London, he wrote his three contributions to comparative psychology, namely, *Animal Intelligence* (Romanes 1882),

*Mental Evolution in Animals* (Romanes 1883), and *Mental Evolution in Man* (Romanes 1888).

During the last part of his life, Romanes put forward his new mechanism for animal speciation, which he named “physiological selection.” He suggested that two parents of the same species might possess, in their hereditary transmission materials, a physiological anomaly, one that by chance was roughly identical in the two parents. The offspring of such parents might then possess an anomalous anatomical or physiological characteristic. This characteristic is sufficiently divergent from the parents’ own characteristics for the offspring (who are assumed not to be sterile) to be the start point of a new species. Clearly these views predated genetic theory. It is of great interest that Forsdyke (2001), while working on viruses, came to believe that Romanes’s idea, rejected in his own time, was prescient of modern genetics.

In 1890, Romanes moved to Oxford, partly to take advantage of the new physiological laboratory there, and partly because he felt oncoming ill health. He and his family occupied a sixteenth-century house opposite the imposing gateway of the largest Oxford college, Christ Church. Later, he became a member of this college. In 1892, he was elected to be an honorary member of his old college at Cambridge, Gonville, and Caius College. At Oxford, he made friends with several clergymen including the Rev. Charles Gore and the Rev. Aubrey Moore, as well as his friend from childhood the Very Rev. Francis Paget. Shortly after arriving, he tried to persuade the university to offer an honorary degree to Francis Galton (1822–1911). He also provided funding for a Romanes Lecture to be delivered at Oxford annually.

Early warnings that Romanes was suffering from a brain disorder included headaches, disturbed vision, and a temporary left hemiplegia. Schwartz (2010, pp. 679–680) tentatively supported Forsdyke’s conclusion that Romanes suffered from a brain tumor. Romanes was advised by doctors, among whom was the neurologist Hughlings Jackson (1835–1911), to stop working. In a letter he claimed he was advised to make his “rule of life” that of a “tortoise”

(Romanes 1896/1898, p. 346). He spent time in Bohemia, Bavaria, Madeira, and the south of France in order to convalesce. During this period, he elaborated on some writings about religion he published as a student. He prepared notes for a projected book to be titled *A Candid Examination of Religion*, published under the pseudonym “Metaphysicus”; these notes were edited by Rev. Charles Gore and appeared posthumously as *Thoughts on Religion* (Romanes 1895). He also accepted frequent visits from his clergymen friends during his final months. On 23 May 1894, at the age of 46, he had a cerebral hemorrhage, from which he died within 1 h. He was buried at Holywell Cemetery (Plot E. 225) in Oxford. He is memorialized in a window in the chapel of Gonville and Caius College, Cambridge.

Summaries of his life and correspondence are provided by E. R. Romanes (1896/1898) and Schwartz (2010). An invaluable account of Romanes’s contributions to neuroscience and to genetics is provided by Lesch (1976), who lists several locations containing archival materials. Summaries of Romanes’s achievements as a comparative psychologist are provided, among others, by Boakes (1984, Chapter 2), Richards (1987, Chapter 8), Murray (1988, pp. 261–271), Wozniak (1999), and Thomas (2012). Brief outlines of his views on the evolution of language are provided by Romanes (1889/1897) himself, Carter (1899), and Kroll (1986).

## Romanes’s Theory of the Evolution of Human Intelligence

In *Animal Intelligence*, Romanes (1882) collected evidence of the kinds of problems that individuals of a wide variety of species were capable of solving. Most of the accusations that Romanes relied too heavily on anecdotal evidence, or was anthropomorphic in his explanations of animal behavior, are based on passages from the last half of *Animal Intelligence*. We know, however, that Romanes preferred to collect experimental data on animal behavior rather than rely on anecdotes. Indeed, in his wife’s biography of him, she stressed that

some anecdotes were rejected from the book because Romanes felt that the evidence was questionable (Romanes 1896/1898, pp. 200, 207). About half the book was devoted to invertebrates such as marine animals and insects. Their small size, rapidity of breeding, and ease of upkeep allowed earlier investigators to experiment on the abilities of these creatures to adapt to unusual environments or to overcome obstacles. Anderson (2001) reviewed some of this Victorian research on insect behavior. She demonstrated how it influenced the way in which some scientists conceptualized animals as being more “machine-like” than humans.

Romanes also reported on the learning and problem-solving abilities of birds and mammals, up to and including the primates. He carried out some experimental work with monkeys (both at the zoo and in his sister’s house); he was one of the first to describe how a monkey responded on seeing itself in a mirror (Romanes 1882, pp. 478–479, 495–496). In his chapter on dogs, he discussed an experiment by Darwin apparently showing that a dog could “recognize” Darwin after not seeing him for 5 years (p. 438). He also related an anecdote sent to Darwin from Canada indicating that dog teams pulling sleds would fan out over the ice on a lake in order to distribute their weight more evenly (p. 482).

In *Mental Evolution in Animals*, Romanes (1883) put forward a theory of the evolution of problem-solving behavior and of learning abilities; this theory depended on the assumption that the more sophisticated a species was at problem-solving and learning, the more highly developed its nervous system. He asserted that a high level of development in the nervous system could be displayed in terms of three main characteristics. First, there was the ability to experience a wide variety of emotions; for example, Romanes believed that more advanced animals (e.g., dogs and apes) were capable of experiencing sophisticated emotions such as jealousy, deceitfulness, or vengeance. Second, there was the ability to learn, recognize, and adapt behavior to difficult environmental circumstances; these included tool-using, detour behavior and cooperative behavior. Third, there was the ability to regulate,

control, and plan future actions; for example, whether to fight or flee when confronted by a predator.

This classification of characteristics dovetailed neatly into “emotion, cognition, and conation,” sometimes called “feeling, knowing, and willing,” that was standard in the teaching of psychology by the end of the nineteenth century (see, e.g., Sully 1888). This classification scheme was introduced in the eighteenth century by German-speaking psychologists including Moses Mendelssohn (1729–1786) and J. N. Tetens (1736–1807). Romanes’s scheme was illustrated by a pull-out chart reproduced in full by Boakes (1984, p. 29) and by Murray (1988, pp. 266–267).

The pull-out chart was divided into 50 horizontal levels. Apes and dogs were ascribed intellectual levels located at about level 28. A human baby aged 15 months was speculated to have a brain that had matured to about level 28 as well. The rationale for Romanes’s scheme was as follows. Romanes believed that life originally consisted of organisms possessing only excitability; however, because excitability had different levels of comfort (at the extremes were pain and pleasure), increasing capacities for sensory discrimination and refinement of movement emerged. Both capacities were mediated by “neurility,” that is, by the evolution of a “conductile” nervous system. In primitive animals, the nervous system operated in an essentially reflex-like way. Animals with highly developed nervous systems, thanks to the evolution of a complex brain, were capable of controlling individual body parts.

As a frontispiece to *Mental Evolution in Man* (1888), Romanes reproduced the pull-out chart of *Mental Evolution in Animals* (1883) without any changes. He presented arguments to show that language in humans had evolved naturally and gradually from its origins in animal vocalizations. There was no sharp separation between humans and animals. There was no “Rubicon,” as the Oxford philologist Max Müller (1823–1900) had called it. Müller wrote that “man speaks, and no brute has ever uttered a word. Language is our Rubicon, and no brute will dare to cross it” (Müller 1866, p. 392). The orthodox Judeo-Christian religious view, based on the book of Genesis, was that humans were created, after the animals and

separately from them, in “God’s own image.” Humans were also uniquely endowed with language. Greenblatt (2017) reviews the impact of Genesis on theories of the origin of language. The countervailing view, still unorthodox in Romanes’s time, was that humans were simply another species of animal, and that it was a challenge for science to spell out how language may have evolved in a continuous manner from the vocalizations of animals to the utterances of humans.

The gist of Romanes’s conceptualization of human language was that it differed from animal communication in three particular ways. First, although it is true that human vocal communications and animal vocal communications both use vocal articulations as “signs” that represent some event in reality, humans are able to use vocal signs as signifiers of a much wider variety of events than is the case for animals. In order to explain why this is so from an evolutionary standpoint, Romanes insisted that it was an outcome of the evolution of a human brain capable of a wider variety of cognitive processing than was possessed by the brain of any animal. He stated that the most fruitful approach to a theory of the evolution of language begins with cognitive psychology, rather than with a study of grammar or another subdiscipline of linguistics. The same viewpoint is maintained by modern writers on the evolution of mind (e.g., Paivio 2007).

Second, Romanes claimed that the human brain had attained a level of cognitive development that allowed its owner to think about (and represent in language) events and things not present in the here-and-now. Although it may appear that few animals have this capability to the same extent as humans, there is evidence that suggests that some animals (notably dogs and primates) do have an elementary form of this ability (Suddendorf and Whiten 2001). The stimuli that humans can respond to are divided into (perceptual) stimuli that are currently present and (memory) representations of stimuli that are not currently present. From a language point of view, Romanes contended that the invention of certain *words* facilitated communication between humans about present events and past events.

Third, Romanes suggested that another way in which human cognitive development differs from

that of animals concerns the conceptualization, by a human, of his or her self. The study of cognitive development in humans indicates that somewhere around the age of 2 or 3, the typical human infant develops a “sense of self,” by which is here meant “self-consciousness.” One of the effects of becoming self-conscious is that one vastly enhances the number of possible stimuli that can be represented in memory and thereby linked with one’s self-concept.

Romanes used memory as a unifying device for developing a consistent model of the above relationships between cognitive and linguistic competence. In a brain that has developed minimal memory, a sensation aroused by a present stimulus quickly dies away when the stimulation stops. Sometimes, however, the sensation persists in a form of “sensory after-effect.” At more advanced levels of development, memory becomes sophisticated enough for the animal to detect that two successive stimuli are different. Romanes believed that, at a slightly more advanced level, an animal could detect that two successive stimuli were identical. When an animal sees that two successive stimuli are identical, and also remembers the emotion associated with the earlier stimulus, a major step forward is taken in the evolution of memory. It allows a bird not to eat a particular caterpillar because, when it had seen the same kind of caterpillar before and eaten it, the experience was aversive. It allows a deer to remember that the last time it was in a certain thicket, it was threatened by a predator. When a given stimulus situation is associated with a particular emotional response, and the situation is repeated in the animal’s experience, the repeated situation (which is in the here-and-now) can elicit a learned emotion.

Romanes argued that English language was lacking a convenient scientific term for this kind of associative memory. In everyday speech, the term “percept” was appropriate for describing what an animal or human experienced while sensing events of the here-and-now. The term “concept” was appropriate for describing what a human adult experienced while thinking about events not in the here-and-now or about abstract ideas. There was, however, no convenient word to describe what an animal or pre-linguistic human

baby experienced when something in the here-and-now elicited an emotional memory. So Romanes (1888), in Chapter 3 of *Mental Evolution in Man*, invented the word “recept” to refer to this intermediate stage of ideation.

Romanes divided recepts into two broad categories. Lower recepts comprised what we now call conditioned emotional responses. They are shared by animals and by pre-linguistic human infants. Higher recepts are special cases of learned responses in which situations can evoke vocal responses that indicate that a child can remember, not only that a situation had occurred but that it was associated with the learning of one or more words. For example, a child may see her sister and a cat simultaneously in the room. She has learned words for “sister” and “cat,” and can say aloud those words. These are learned responses of a verbal, rather than an emotional, kind. This is the level of development that Romanes called “pre-conceptual” and is typically found in a 2- or 3-year-old child. It is not found in animals. The question of whether a parrot, who has learned a given sound in a given situation, is using language, was discussed in depth by Romanes; he argued that the parrot was demonstrating lower receptual behavior, rather than higher receptual or conceptual behavior. It was, therefore, inappropriate to assert that the parrot possessed “language.”

When a child has acquired the understanding that words stand for objects and starts learning words in order to label situations in the here-and-now, the child is moving into the acquisition of concepts. At this stage, the child is also becoming self-conscious. Romanes linked the “conscious” learning of new vocabulary by a child with the acquisition of a “consciousness” of herself. Moreover, her brain is developing to a level at which words that were used to label situations in the here-and-now could be used in a more sophisticated way, namely, to refer to objects that were perceived in the past but are not present in the here-and-now.

## The Secondary Literature on Romanes

Carter (1899) published a critical account of Romanes’s theory of the evolution of intelligence.

Two of her arguments deserve particular attention. First, she objected that Romanes’s invention of the word “recept,” while in some ways welcome, was not defined rigorously enough to form a solid foundation for a theoretical superstructure as detailed as was Romanes’s. It can be added that the various subclassifications of kinds of recepts that were included in *Mental Evolution in Man* were difficult for readers to grasp and retain. This was acknowledged by Romanes (1889/1897) himself.

Second, Carter (1899) pointed out that Romanes often narrated anecdotes about individual problem-solving achievements in infrahuman species. Carter suggested that this led him to imbue animals with high levels of problem-solving or emotional intelligence. Knowledge of an animal’s prior history has to be available before a claim can be made that the animal is unusually gifted at problem-solving. In many textbooks of introductory psychology, or of comparative psychology, published in the twentieth century, Romanes was castigated for being “anthropomorphic,” that is, for being too ready to ascribe human-like intelligence to animals. In the twenty-first century, however, researchers have been more lenient in accepting that anecdotal evidence can sometimes validly be used as evidence of a high level of cognitive competence in animals (De Waal 2019; Godfrey-Smith 2016, Chapter 6).

## Georgia State University's Language Research Center

David A. Washburn<sup>1,2</sup> and Duane M. Rumbaugh<sup>2</sup>

<sup>1</sup>Covenant College, Lookout Mountain, GA, USA

<sup>2</sup>Georgia State University, Atlanta, GA, USA

The Language Research Center (LRC) is a primate-research facility operated by Georgia State University (GSU). Physically located on over 55 acres of forested land near Atlanta, GA, USA, the LRC has provided resources for the noninvasive, longitudinal study of behavior and cognition of nonhuman primates, primarily resident colonies of chimpanzees (*Pan troglodytes*), bonobos (*Pan paniscus*), rhesus monkeys (*Macaca mulatta*), and capuchin monkeys (*Sapajus apella*). These animals participate voluntarily in behavioral research (they are not deprived of food or fluid for purposes of testing, nor are they exposed to aversive conditions to make them work). Additionally, the LRC has supported comparative research with human adults and children – including intervention research, for example, with youth with developmental disabilities – throughout its history.

Scientists from psychology, neuroscience, biology, anthropology, philosophy, linguistics, computer science, and other departments within GSU, and from dozens of other universities worldwide, study the unique animals at the LRC on a wide range of topics. (Note: Humans are animals, primates, and apes too; however, these terms here will refer to nonhuman animals, primates, and apes.) What makes these animals particularly interesting to researchers are the training histories and testing experience that each possesses. This includes, in the case of some of the apes, symbolic-communication training that has yielded competencies in comprehension and production that both advance understanding of what organisms can do with language that they could not do without it, and also challenge the uniqueness of human competencies in language and other domains. Working with academic departments at GSU and other institutions, the LRC also serves an educational mission, allowing students at the undergraduate, graduate, and postdoctoral levels to learn about primates and the methods of noninvasive primate research at the behavioral, social, cognitive, neural, biological, and ecological levels of analysis. LRC student and faculty scholars have also reported findings that educate the public through the popular media (print and electronic) and in textbooks and other educational materials for children, youth, and adults, in a large number of languages and cultures. Among these findings are principles of psychological well-being in nonhuman and human primates; that is, a primary aim of LRC scientists has always been to understand and to promote psychological health in humans and in the non-human animals that partner with those scientists in the pursuit of discovery.

## History

The LRC was founded in 1981, but its roots extend a decade earlier. Two of the most important individuals in this history were a comparative psychologist named Duane M. Rumbaugh and a chimpanzee named Lana, who was the focal participant in the Language ANalog (LANA)

Project, established by Rumbaugh and a team of collaborators at the Yerkes Regional Primate Research Center, Emory University (Atlanta, GA, USA). In 1970, Rumbaugh, then the Associate Director and Chief of Primate Behavior at the Yerkes Center, proposed an innovative investigation of whether apes could learn and use a human-like language. Although this question had been studied by others (Hillix and Rumbaugh 2004), Rumbaugh believed that an unparalleled level of experimental control over training and potential confounding variables could be achieved by automating language training through the use of computers, which were still a relatively new technology. Working with a biomedical researcher, computer programmer, electronics technician, psycholinguist, research technicians, and a developmental psychologist, Rumbaugh developed a computer-based keyboard system in which each key would be a unique visuospatial symbol (called a lexigram), corresponding to an English word (Rumbaugh 1977). Pressing any key would cause it to illuminate, and the appropriate symbol also to display on a panel of projectors located above the keyboard. Dispensers, televisions, and other devices were connected to the keyboard so that the computer could automatically respond to key-presses by delivering food, dispensing juice, playing music, or whatever action was indicated by the selected keys. However, depression of single keys left too much room for interpretation and potential experimental bias: If a chimpanzee pressed the key for WATER, was the animal requesting water, labeling the liquid on the floor as water, commenting on water it previously received, or something else? To avoid this ambiguity, a grammar (called Yerkish, after Robert Yerkes) was developed to determine the rules for symbol sequences, and a series of stock sentences (e.g., “PLEASE MACHINE GIVE \_\_\_\_\_ PERIOD” where “PLEASE” and “PERIOD” were used to start and end requests, and any number of deliverable objects could be inserted in the blank) became the initial targets of ape-language training.

In 1973 and with funding from the National Institute of Child Health and Human Development (NICHD), LANA Project scientists began

training the 2½-year-old chimpanzee to use the lexigram keyboard. Lana learned to use the symbols and the Yerkish grammar to make requests, to answer questions, to ask questions, to comment, and generally to communicate with the PDP8 computer and the researchers (particularly Dr. Timothy Gill, then a graduate student who served as Lana's primary trainer). Lana's performance quickly garnered attention from both the scholarly community and the public, with reactions ranging from highly critical (e.g., "Aping language"; Wallman 1992) to extremely positive (e.g., "Computer helps chimpanzees learn to read, write and 'talk' to humans"; Rensberger 1974) and all points in between (see Hillix and Rumbaugh 2004 for a review of both reactions). In any case, the findings from Lana were sufficiently encouraging, and raised significant questions for further inquiry, that additional chimpanzees were obtained for lexigram training.

In 1975, chimpanzees Austin and Sherman were assigned by the Yerkes Center to the ape-language project. Rumbaugh, postdoctoral research Sue Savage, and their research team endeavored to build on the strengths of the LANA Project while addressing the weaknesses. The lexigram-based computer keyboard was retained, but the Yerkish stock sentences were abandoned. Interactions with human caregivers and researchers were still studied, but the emphasis was shifted to social communications between the two apes. Communicative production was still measured, but the real focus was comprehension, or what the symbols might mean to the chimpanzees. Like Lana, Sherman and Austin used the symbols in a variety of contexts; however, they showed more convincing evidence than did Lana of conceptual understanding of the lexigrams as representing referents that were not physically present, and of using the computer keyboard to solve problems that could not be solved without symbol-based communication (Savage-Rumbaugh 1986).

Although the Lana, Sherman, and Austin research of the 1970s predates the founding of the LRC, the success of the work with these apes and the investigators' success in securing extramural funding for the research were critical for the

events that would follow. On September 20, 1979, a memorandum was distributed to the various Deans and Department Chairpersons at GSU. The university had been given several hundred acres of land in nearby Dekalb County, GA, by the federal government, under the condition that the land be used for significant academic purposes. GSU was using the land for sports and recreation but was feeling pressure to expand the academic use of the property. The memorandum served as a call for proposals.

Duane Rumbaugh, who had accepted appointment as Professor and Chair of Psychology at GSU in 1971, pitched the idea of moving the ape-language project from the Yerkes Center to this property. Additionally, the complementary language-intervention work that had grown out of the LANA Project would also move from the Georgia Retardation Center to that same location. This intervention research with children and young adults with intellectual disability (what was, at the time, called mental retardation) involved training the nonspeaking youths to use and to understand keyboard-based lexigrams, applying the principles of language learning that had been gleaned from work with apes (Rumbaugh 1977). Together, the NICHD-funded ape and human "Language Formation Study" would require vivarium, laboratory, office, and support facilities adequate to continue the work in a single site. Although a requirement for any proposed academic use of the Dekalb property was that the proposals utilize available resources, Rumbaugh argued that GSU should purchase a 3,500-sq ft prefabricated building that would support the parallel research projects. In a memorandum to the GSU Associate Vice President for Academic Affairs (October 20, 1979), Rumbaugh wrote, "To have all of the work going on in the same situation would maximize our use of people, equipment, and, most important of all, it would make possible optimal communication between the chimpanzee and human child projects."

By December of that year, Rumbaugh had secured commitments from the GSU Foundation to assign more than 50 acres of land to the Language Formation Study and to commit \$130,000

to construct a building of approximately 6,000-sq ft. Shortly thereafter, construction began with foundation and university support. Fred King, Director of the Yerkes Center, agreed to allow the apes to move to the GSU property, although Yerkes would retain ownership of the animals for more than a decade. The Georgia Retardation Center at the Georgia Regional Hospital of Atlanta agreed to permit two children at a time to be transported by bus to the GSU property for training and testing. NICHD approved the relocation of the science to the new facilities. Research began on the property in the spring of 1981. A few months later, the GSU Foundation Board of Directors toured the new facility. The Board of Regents of the University System of Georgia approved the LRC as an officially designated research center, the first at GSU. A brass plaque unveiled at the Fall 1981 dedication of the center acknowledged the support from all of these parties and revealed the LRC slogan: "So that together we might learn of language."

In the dedication of the LRC, Rumbaugh, Savage-Rumbaugh, and their colleagues indicated that the center was founded on five research assumptions: (1) that there is continuity between chimpanzees and humans in learning and other cognitive competencies; (2) that it is important for research to define where the species do differ in these competencies or in the processes by which the organisms come to gain them; (3) that comparative psychological inquiry affords significant and singular power for investigating how cognitive skills emerge; (4) that biology and experience interact to produce the emergence of cognitive competencies; and (5) that computer technology is uniquely useful in the comparative approach. These five assumptions continue to underlie research at the LRC. Similarly, the original statement of LRC research goals is as accurate today as when it was written on September 15, 1981: Goal 1. To study the emergence of cognitive skills; Goal 2. To define the parameters of training or teaching that cultivate particular cognitive skills; and Goal 3. To extrapolate those principles into research with humans, particularly those with developmental delays.

## LRC Facilities

Today, the LRC is a campus comprised of four laboratory/vivarium buildings and several research-support structures, situated on more than 50 acres of forest. For much of its history, the LRC employed the forest as laboratory space as well, with researchers traveling with lexigram-trained apes through its many trails to treehouses, camp sites, the river, and other locations where food might be available and where language lessons might be conducted. The original 6,500-sq ft building constructed at the LRC (representing a significantly larger investment from GSU and its foundation than their original commitment!) was designed to support chimpanzee (and, subsequently, bonobo) research in half of the structure, with indoor/outdoor caging, laboratory, and kitchen areas. The other half of the building was originally used for the child-language project and provided workspace for LRC faculty and students. In time, the language-intervention research moved out of the laboratory and into the children's homes and schools (e.g., Ronski and Sevcik 1991), and the apes moved into new buildings constructed for them (described below), so that the LRC main building now primarily serves office and laboratory functions for the faculty, staff, and students at the center.

The Lanson Building is a dedicated laboratory and vivarium for chimpanzee research. It was named for chimpanzees Lana and the son (thus Lanson) named Mercury she delivered there. It also served as primary home to other apes. The Sonny Carter Life Sciences Laboratory (SCLSL) is a dedicated laboratory/vivarium used primarily for monkey research. It was named in 1991 for astronaut Manley L. "Sonny" Carter (1947–1991), a Georgia native and Emory University alumnus who served as the liaison for the National Aeronautics and Space Administration (NASA) to the LRC for a multidisciplinary, international research project on the effects of space-flight on rhesus monkey behavior and physiology, funded by NASA grants. The CapLab was originally constructed as a quarantine and vivarium building for bonobos, which lived and worked in

the “ape area” of the main building as well as this new laboratory. A chain-link tunnel connected the two structures, allowing the apes to move between them securely. When the bonobos moved in 2004–2005 to facilities constructed for them at the Great Ape Trust of Iowa (now Ape Cognition and Conservation Initiative), the quarantine building was converted for housing and testing capuchin monkeys.

These buildings provide over 12,000 sq ft of indoor/outdoor housing and testing space, with another 7,000 sq ft of research support (e.g., office, prep) space. Additionally, maintenance shop, cage washing, and storage buildings are also available on campus. The LRC also leases an adjacent residence that is used as rental space for students, postdoctoral fellows, and visiting scientists.

## LRC Animals

The LRC is not merely a brick-and-mortar (and caging) compound; it is also, indeed primarily, defined by the resident animals that live and work in those facilities, and by the people who work with them. Since 1981, the LRC has served as home for 5 chimpanzees, 14 bonobos, 2 orangutans (*Pongo pygmaeus*), and dozens of rhesus monkeys and capuchin monkeys. This census includes many nonhuman primates that are well known and widely represented in the literature. Already discussed were Lana (1970–2016), Austin (1974–1996), Sherman (1973–present), and Mercury (1986–2016). The chimpanzee Panzee (1985–2014) and the bonobo Panbanisha (1985–2012) were co-reared at the LRC in a study designed to disentangle the contributions of species and experience on various cognitive competencies, including lexigram use and the comprehension of spoken English (Hillix and Rumbaugh 2004). Other bonobos raised at the LRC, notably Kanzi (1980–present) also demonstrated impressive cognitive skills, including the comprehension of lexigrams and spoken English under experimentally controlled tests (Savage-Rumbaugh et al. 1993), although his adopted mother, wild-born Matata (~1970–2014) failed

to learn these skills. The two orangutans also contributed data to published studies before they retired, Mari (1981–present) to the Center for Great Apes in Florida, and Madu (1983–present) to Zoo Atlanta, where she is now a featured attraction for her skills as a surrogate mother. Rhesus macaques Abel and Baker were the first two monkeys to master the joystick-manipulation skills required to respond to computer-generated stimuli in a series of game-like computerized tasks (Rumbaugh et al. 1989), and thus were pioneer animals in the development of the computer-test system, used originally with Sherman and Austin, and discussed further below. Many other rhesus monkeys (e.g., Hank, Gale, Willie, Murph, Lou, Hans, Obi, Chewie) have also contributed data to the literature, as have dozens of capuchin monkeys (e.g., Drella, Gabe, Griffin, Liam, Lily, Nala, Logan, Wren, and others) generously transferred to the LRC from the colonies of Frans de Waal, Dorothy Fragaszy, and Stephen Suomi.

## LRC Scientists and Caretakers

As indicated above, one cannot describe the LRC without discussing the innovative and dedicated people who have invested time and effort into understanding human and nonhuman primate behavior and cognition, and who have worked to ensure that the nonhuman animals that participate in this research are as healthy and as happy as possible. Any list of faculty, staff, and students who have worked in significant capacities at the LRC will necessarily be selective, and yet one cannot fully appreciate the impact of the center without recognizing some of the individuals associated with it. The studies conducted by these researchers have frequently employed animals other than those at the LRC, but each has made important contributions to the literature with LRC animals, and most have also attracted grant support to the center. Duane Rumbaugh was the founding Director and served in this role until his retirement in 2001. For many of those years, Sue Savage-Rumbaugh functioned as Associate Director. From 2001–2019, David Washburn directed the LRC, with Michael Beran—and his

research programs on numerical cognition, memory, cognitive control, and other topics (e.g., Beran 2004; Beran et al. 2014, 2016—as the Associate Director since 2012. Additional senior researchers include Sarah Brosnan, whose creative investigations of social cognition (particularly inequity, cooperation, and economic decision making) span all four of the primate species (capuchins, rhesus, chimpanzees, and humans) studied at the LRC. Charles Menzel has directed research on memory and spatial cognition. William (Bill) Hopkins has published extensively on neural and genetic differences across species, and their relation to behavior. J. David Smith and Barbara Church examine species similarities and differences in categorization and metacognition (e.g., Smith et al. 2016a, b). Previous senior researchers at the LRC have included MaryAnn Ronski (language intervention with special populations of children and adults), Rose Sevcik (language acquisition in apes and children), Robin Morris (functional lateralization of behavior), James Pate (learning and memory), Lauren Adamson (language development), Kirk Richardson (learning), and Michael Owren (vocal communication). Many other GSU faculty have collaborated on LRC publications and grants, including Roger Bakeman, Robert Latzman, Becky Williamson, Chris Conway, Tricia King, Marise Parent, Yanqing Zhang, Mukesh Dhalama, and R. Thompson Putney. Investigators from institutions outside of the LRC have also collaborated on research at the center, including Emil Menzel (problem solving), Patricia Greenfield (language), Dennis Molfese (cognitive neuroscience), Michael Tomasello (imitation), Dorothy Frigaszy (spatial cognition), Christian Argrillo (judgment), Kimberly Espy (executive functioning), Redouan Bshary (cooperation), Franz De Waal (social cognition), Gregory Ashby (categorization), Tara Stoinski (face recognition), Andrew Whiten (imitation), Steven Shapiro (face recognition), Anika Paukner (social cognition), Bart Wilson (economic decision making), Hani Freeman (primate personality), Joan Silk (prosociality), Bob Cook (categorization), Drew Rendall (auditory communication), Jennifer Vonk (comparative cognition), Carla Krachun and

Robert Lurz (theory of mind), Nicholas Toth and Kathy Schick (tool construction), Michael Posner and Mary Rothbart (development of executive attention), and countless others. Dr. Sarah Brosnan and Dr. Michael Beran are currently co-directors of the LRC.

In partial fulfillment of the “academic use” that motivated the original center proposal, the LRC has facilitated the education and training of many students. Washburn (attention), Hopkins (lateralization), Sevcik (language), and Beran (numerical cognition) were graduate students at the LRC years before they became senior scientists. Other graduate students who completed LRC-supported doctoral research include Kim Bard (behavioral development), Tom Smith (language research), Darlene Meador (discrimination learning by children), Karen Brakke (differences between bonobos and chimpanzees), Heidi Lyn (language), Jared Taglialatela (vocal production), Krista Wilkinson (language intervention with children), Wendy Shields (judgments of knowing), Joshua Redford (study-time allocation), Laurent Pretot (social cognition), Justin Couchman (self-agency), Mariana Coutinho (uncertainty), Jonathan Gulledge (numerical cognition by macaques), Audrey Parrish (perception), Kate Talbot (face recognition), Megan Hoffman (memory), Darby Proctor (decision making), Emily Marr (numerical cognition), Timothy Flemming (analogical judgment), and Lisa Heimbauer (speech comprehension). Hundreds of other graduate and undergraduate students have benefitted from LRC research resources. Postdoctoral researchers at the LRC over the years include Shelly Williams, Kenneth Sayers, Bonnie Perdue, Dan Cerutti, Dalila Bovet, Carole Parron, Claudio Cantalupo, Samuel Fernandez-Carriba, Lydia Hopper, Marcela Benitez, Emily Klein, and Travis Smith.

This list omits many other contributors, but perhaps none so important as the staff members who have provided care for the animals. Some, like Assistant Director of Animal Resources John Kelly, Liz Pugh, Janine Murphy, Kelly Leverett, Ted Evans, and others have been recognized as coauthors on scholarly contributions, but many other people merit acknowledgment for the

animal care and research assistance they have provided. It takes a village to raise, teach, study, and care for nonhuman primates, and the LRC has been fortunate to attract and retain a highly dedicated staff.

## LRC Support

Administratively, the LRC is a unit of the College of Arts and Sciences at GSU, which provides generous support. GSU and its foundations own the land and the animals and have also supported the center extensively. With respect to extramural funding, LRC scientists have attracted grants from multiple agencies in the National Institutes of Health (NIH), the National Science Foundation (NSF), NASA, Templeton Foundation, Wenner-Gren Foundation, McDonnell-Pew Foundation, Leakey Foundation, and other agencies. Primary support for LRC research has been provided through several program-project (P01) awards from the Eunice Kennedy Shriver NICHD (HD06016, HD38051, and HD060563), representing more than four decades of continuous funding for investigations with nonhuman primates of issues related to child health and development.

## LRC Contributions

Since the LRC was founded, its research team has averaged more than 20 published articles and chapters per year. As suggested by the topics associated with the collaborators listed above, the questions reflected by these scholarly products span the comparative study of behavior (although paradoxically, the topic of language has become less central in the LRC research portfolio, as scientists have increasingly broadened their questions to other competencies). Some of the most influential findings from these studies are that apes use lexigrams to label or name objects, treat the symbols as equivalent to the objects they represent, and remember the meanings of lexigrams and other symbols, even if they have not used the symbols for many years (e.g., Savage-Rumbaugh 1981, 1986; Beran et al. 2000; Beran and Heimbauer 2015). Language-experienced apes
